**Tricyclic antidepressants.** Two controlled trials of TCAs in male combat veterans with DSM-III-defined ([American Psychiatric Association 1980](#)) PTSD showed benefit for amitriptyline and imipramine ([Davidson et al. 1990](#); [Kosten et al. 1991](#)). A recent report suggests that the now-ignored TCAs deserve reappraisal, given their efficacy in populations with traditionally SSRI-resistant PTSD ([Davidson 2015](#)) and the superiority of desipramine over paroxetine in improving drinking-related measures in male veterans with comorbid alcohol-related disorders ([Petrakis et al. 2012](#)).

**Monoamine oxidase inhibitors.** In a study of male combat veterans, [Kosten et al. \(1991\)](#) compared phenelzine (15–75 mg/day) with placebo and found a 45% decrease in Impact of Event Scale (IES) scores from baseline for phenelzine, compared with a 5% decrease for placebo, but no improvement was noted in depressive symptoms with

either treatment. The RIMA brofaromine has been assessed in two controlled trials of PTSD: a U.S. sample composed predominantly of combat veterans ( $n=114$ ) ([Baker et al. 1995](#)) and a civilian European sample with few veterans ( $n=68$ ) ([Katz et al. 1994-1995](#)). The U.S. study failed to show a difference between the treatments, and findings from the European study were mixed. Finally, the RIMA moclobemide was assessed in 20 subjects with PTSD meeting DSM-III-R ([American Psychiatric Association 1987](#)) criteria ([Neal et al. 1997](#)). Following 12 weeks of treatment, 11 subjects no longer met the full PTSD criteria, providing a signal that the drug might be effective in PTSD.

### **Selective serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors.**

Three controlled trials support the efficacy of fluoxetine in PTSD. In these studies, fluoxetine was administered at dosages of 20-80 mg/day for 5-12 weeks in samples including both civilians and combat veterans with PTSD meeting DSM-III-R ([Connor et al. 1999](#); [van der Kolk et al. 1994](#)) or DSM-IV ([Martenyi et al. 2002a](#)) criteria. Significant improvements in clinician-rated structured interviews from baseline to end of treatment were noted, as were significant improvements in resilience and reduction in disability ([Connor et al. 1999](#)). Symptomatic improvement was noted as early as week 6 ([Martenyi et al. 2002a](#)).

Two studies of maintenance therapy with fluoxetine over a period of 1 year have shown reductions in the rate of relapse, as compared with placebo substitution ([Davidson et al. 2005](#); [Martenyi et al. 2002b](#)).

Sertraline has been compared against placebo in 10 trials, and positive results have emerged in 3 of these

([Brady et al. 2000](#); [Davidson et al. 2001](#); [Panahi et al. 2011](#)), while 7 were either ambiguous or negative. A pooled analysis of the positive trials showed an early effect on anger at 1 week ([Davidson et al. 2002](#)). This finding is of significance, given that angry temperament can be associated with violence and a greater risk for cardiac events ([Williams et al. 2001](#)), as well as increased heart rate and blood pressure, in PTSD ([Beckham et al. 2002](#)). A recent placebo-controlled trial of sertraline in Iranian veterans of the Iran-Iraq war showed that sertraline was superior to placebo and was well tolerated ([Panahi et al. 2011](#)). Other short-term studies of sertraline in PTSD have been negative ([Brady et al. 2005](#); [Davidson et al. 2006b](#); [Friedman et al. 2007](#); [Tucker et al. 2003](#)) or inconclusive ([Zohar et al. 2002](#)). A trial in children by [Robb et al. \(2010\)](#) failed to show any difference between drug and placebo.

Continued sertraline treatment over 9 months was associated with sustained improvement in more than 90% of subjects, and more than 50% of initial nonresponders responded with continued treatment ([Londborg et al. 2001](#)). Improvement was sustained over 15 months, with a relapse rate of 5% for sertraline and 26% for placebo, suggesting that the drug provides prophylactic protection against relapse ([Davidson et al. 2001](#)). Sertraline was also effective in improving quality of life and reducing functional impairment, with more than 55% of patients functioning at levels within 10% of the general population. These gains were maintained with long-term treatment, whereas treatment discontinuation was more likely to lead to deteriorating function, although not to levels observed prior to treatment ([Rapaport et al. 2002](#)).

The efficacy of paroxetine in PTSD has been shown in two 12-week controlled multicenter trials, including flexible-

dose ( $n=307$ ; paroxetine 20–50 mg/day) ([Tucker et al. 2001](#)) and fixed-dose ( $n=451$ ; paroxetine 20 mg/day or 40 mg/day) ([Marshall et al. 2001](#)) regimens. Compared with placebo, paroxetine produced significant improvement in overall PTSD symptomatology, individual symptom clusters, and functional impairment. Response rates ranged from 54% to 62% for paroxetine, compared with 37% to 40% for placebo.

Findings from two open-label studies of fluvoxamine at dosages of 100–250 mg/day—an 8-week study in civilians ( $n=15$ ; [Davidson et al. 1998](#)) and a 10-week study in combat veterans ( $n=10$ ; [Marmar et al. 1996](#))—showed that the drug was effective in treating PTSD symptoms. Treatment with fluvoxamine (mean=194 mg/day) also was associated with significant improvement in autonomic reactivity, with reductions in heart rate and blood pressure on exposure to trauma cues to levels that are indistinguishable from those of control subjects ([Tucker et al. 2000](#)). These findings are encouraging, although larger controlled trials are needed to determine the efficacy of the drug in PTSD.

Two large multicenter studies have established efficacy for venlafaxine XR up to 300 mg per day, in one case for as long as 6 months. Rates of remission exceeded 50% in the longer-term trial, and resilience was significantly improved in one of the two studies ([Davidson et al. 2006a, 2006b](#)).

In summary, the SSRIs are efficacious in the treatment of PTSD, and paroxetine IR and sertraline are approved for PTSD treatment. SSRIs and SNRIs show a broad spectrum of activity, with significant reduction in some symptoms as early as 1–2 weeks after treatment initiation, sustained and continued improvement, and in some cases remission, with long-term treatment up to 15 months. These drugs are

generally well tolerated, although some adverse effects (e.g., sexual dysfunction, sleep disturbances, and weight gain) may lead to treatment discontinuation.

**Other antidepressants.** An 8-week controlled trial of mirtazapine in 29 outpatients with PTSD showed a 65% response rate on clinician-rated global assessment with mirtazapine compared with a rate of 20% with placebo, with significant improvement on several measures of PTSD as well as general anxiety ([Davidson et al. 2003](#)).

Six open-label studies of nefazodone in civilians and combat veterans with PTSD have been reported ([Hidalgo et al. 1999](#)). Treatment with nefazodone (50–600 mg/day) over 6–12 weeks was associated with significant reduction in severity of overall PTSD, as well as in each of the symptom clusters. Of particular note was improvement in sleep, which is often disrupted in PTSD and sometimes worsened by treatment with SSRIs. [Davis et al. \(2004\)](#) have demonstrated superior efficacy for nefazodone relative to placebo in combat veterans. However, concerns about potential liver damage have limited the drug's use in PTSD.

## Anxiolytics

Benzodiazepines are often prescribed to treat acute anxiety in the aftermath of a trauma; however, findings have been disappointing. An open-label study of alprazolam and clonazepam in 13 outpatients with PTSD found reduced hyperarousal symptoms but no change in intrusion or avoidance/numbing ([Gelpin et al. 1996](#)). In a crossover design, subjects received 5 weeks of treatment with either alprazolam or placebo followed by 5 weeks of the alternative therapy ([Braun et al. 1990](#)). Minimal improvement was observed in anxiety symptoms overall,

with no improvement in core PTSD symptoms. Clonazepam 2 mg was not different from placebo in controlling nightmares in a 2-week single-blind crossover study in which the test drug was added to preexisting treatment ([Cates et al. 2004](#)). Thus, the evidence does not support the use of benzodiazepines in the management of core PTSD symptoms, even though they appear to be widely used for that purpose ([Mellman et al. 2003](#)). Furthermore, a recent meta-analysis of the efficacy of benzodiazepines in the treatment of PTSD found them to be not only ineffective but also potentially harmful, in terms of increasing the risk of developing PTSD if prescribed after recent trauma as well as worsening aggression, depression, and comorbid substance use ([Guina et al. 2015](#)). Benzodiazepines should therefore be considered relatively contraindicated for use in PTSD or after recent trauma exposure.

## **Anticonvulsants**

[Lipper et al. \(1986\)](#) proposed that the pathophysiology of PTSD may involve sensitization and kindling processes and, to this end, that anticonvulsants might be of therapeutic benefit. In testing this hypothesis, Lipper and colleagues found that 7 of 10 Vietnam War veterans who received open-label carbamazepine (600–1,000 mg/day) for 5 weeks reported improvement, particularly in intrusion and hyperarousal symptoms. Three subsequent open-label studies, two with sodium valproate in combat veterans ([Clark et al. 1999](#); [Fesler 1991](#)) and one with adjunctive topiramate in a civilian PTSD sample ([Berlant and van Kammen 2002](#)), also reported positive effects. However, two more recent double-blind, placebo-controlled trials of divalproex monotherapy in combat veterans with PTSD

were negative ([Davis et al. 2008a](#),  $n=85$ ; [Hamner et al. 2009](#),  $n=29$ ).

Topiramate has received mixed reports in PTSD. An initial trial was negative ([Tucker et al. 2007](#)); however, a more recent double-blind, placebo-controlled trial in 70 civilians (men and women) showed positive effects on re-experiencing and numbing/avoidance symptoms for topiramate at a mean dosage of 102.9 mg/day ([Yeh et al. 2011](#)). Topiramate at dosages up to 300 mg/day in a prospective 12-week, randomized, placebo-controlled, flexible-dose trial also decreased alcohol consumption and cravings and improved hyperarousal symptoms in 30 veterans diagnosed with PTSD and alcohol use disorder ([Batki et al. 2014](#)).

The largest placebo-controlled trial of an anticonvulsant to date found no difference between tiagabine (at a dosage of up to 16 mg/day) and placebo in a 12-week multicenter trial in 232 patients ([Davidson et al. 2007](#)). In a small placebo-controlled trial of lamotrigine (200–500 mg/day) in 15 outpatients ([Hertzberg et al. 1999](#)), a response rate of 50% was noted with lamotrigine, compared with a placebo response rate of 25%.

## Other Treatments

**Antipsychotics.** In a monotherapy trial of olanzapine ([Butterfield et al. 2001](#)), 15 subjects were randomly assigned 2:1 to treatment with olanzapine (up to 20 mg/day) or placebo. No differences were observed between the treatments; however, it is difficult to interpret the findings in this small sample, especially given the high placebo response rate (60%). In a recent small randomized, placebo-controlled trial of flexible-dose olanzapine

monotherapy in a population with non-combat-related chronic PTSD, olanzapine was found to be superior to placebo, though approximately half of the patient sample experienced significant weight gain (Carey et al. 2012). Other reports of antipsychotics are based on augmentation therapy in SSRI partial responders. Several placebo-controlled studies, mainly of augmentation therapy, have found superior efficacy for low-dosage risperidone in both civilian and veteran populations (Bartzokis et al. 2005; Hamner et al. 2003; Monnelly et al. 2003; Reich et al. 2004; Rothbaum et al. 2008), as well as for olanzapine (Stein et al. 2002). In the Monnelly et al. (2003) study, particular benefit was noted for irritability, and in the Hamner et al. (2003) study, psychotic symptoms were relieved. However, a recent large double-blind, placebo-controlled trial of adjunctive risperidone treatment in a patient population with military-related PTSD and SSRI-resistant symptoms found no major benefit for risperidone, although statistically significant changes occurred on some measures (Krystal et al. 2011).

In a double-blind, placebo-controlled monotherapy trial of quetiapine in 80 patients with chronic PTSD, a significant improvement in CAPS scores, as well as in reexperiencing and hyperarousal subscores, was seen by the end of the 12-week trial at an average dosage of 258 mg/day (range 50–800 mg/day) (Villarreal et al. 2016).

**Prazosin and guanfacine.** Raskind et al. (2003) reported encouraging results for intractable PTSD-related nightmares in a placebo-controlled crossover study of prazosin, an  $\alpha_1$ -adrenergic antagonist, at dosages of up to 10 mg/day. The initial findings were confirmed in a second and larger placebo-controlled, double-blind augmentation trial in combat veterans, using dosages of up to 15 mg

daily; benefits were most apparent for nightmares and sleep quality, but the drug also produced greater global improvement ([Raskind et al. 2007](#)). In a randomized, placebo-controlled crossover study of prazosin in 13 patients with civilian trauma-related PTSD, [Taylor et al. \(2008\)](#) found that prazosin significantly increased total and rapid eye movement (REM) sleep time, reduced trauma-related nightmares and awakenings, and improved PCL and CGI scores. A study comparing prazosin with quetiapine for nighttime PTSD symptoms found similar short-term effectiveness for the two drugs but a greater likelihood of treatment discontinuation due to adverse effects for quetiapine ([Byers et al. 2010](#)). A recent randomized controlled 15-week trial in active-duty soldiers showed prazosin to be effective in decreasing global PTSD symptoms and to be well tolerated at maximum dosages of up to 25 mg/day for men and 12 mg/day for women ([Raskind et al. 2013](#)).

In contrast, two placebo-controlled studies of the  $\alpha_2$ -adrenergic agonist guanfacine in veterans with PTSD found no benefit ([Davis et al. 2008b](#); [Neylan et al. 2006](#)).

**Additional approaches.** Given the prevalence of comorbid depression with PTSD and the effectiveness of triiodothyronine ( $T_3$ ) augmentation in some individuals with treatment-refractory depression, it is possible that  $T_3$  augmentation also may be of benefit in PTSD. Five subjects with PTSD taking an SSRI were treated with open-label  $T_3$  (25  $\mu$ g/day) for 8 weeks ([Agid et al. 2001](#)). Improvement was noted as early as 2 weeks, and by the end of treatment, four of the five subjects showed at least partial improvement in depressive symptoms and hyperarousal.

The mechanism for these effects is unknown, and further controlled studies of this augmentation strategy are needed. Cyproheptadine, an antihistaminic drug, was no more effective than placebo for nightmares over 2 weeks in a series of 69 combat veterans with PTSD ([Jacobs-Rebhun et al. 2000](#)). The naturally occurring compound inositol was ineffective in a small placebo-controlled trial ([Kaplan et al. 1996](#)). Innovative treatments with some promise include the NMDA agonist D-serine ([Heresco-Levy et al. 2009](#); [de Kleine et al. 2012](#)) and the neurokinin-1 receptor antagonist GR205171 ([Mathew et al. 2011](#)).

Low-intensity repetitive transcranial magnetic stimulation (rTMS)—in particular, right-sided rTMS applied to the dorsolateral prefrontal cortex ([Boggio et al. 2010](#))—has shown some promise in PTSD, as has acupuncture ([Hollifield et al. 2007](#)). An open trial of electroconvulsive therapy (ECT) in 20 patients with chronic, treatment-refractory PTSD showed improvement in CAPS-rated PTSD symptoms, independent of depressive symptoms ([Margoob et al. 2010](#)). Larger double-blind studies are needed before these somatic treatments can be recommended for PTSD.

An open trial in 166 active-duty soldiers with multiple combat deployments reported that stellate ganglion block led to improvement in PCL scores that was sustained at 6 months ([Mulvaney et al. 2014](#)). However, a recent randomized, placebo-controlled trial of this procedure in 42 military service members with PTSD found no benefit ([McLay et al. 2015](#)).

Ketamine infusion was compared with an active placebo control (midazolam) in a randomized, double-blind, crossover trial in 41 subjects with chronic PTSD ([Feder et al. 2014](#)). The authors reported rapid and significant reduction in PTSD symptoms 24 hours after the infusion, as

well as improvement in comorbid depression. Larger controlled trials are needed to further assess the benefits of this intervention.

CBT has been extensively studied in PTSD and shows overall efficacy ([Bisson and Andrew 2005](#)). In one large well-designed multicenter trial ([Schnurr et al. 2007](#)), the effect size and number-needed-to-treat results for CBT were of the same order of magnitude as those found in comparable trials of antidepressant drugs for PTSD. However, there are only limited data on the combined use of antidepressants and CBT ([Rothbaum et al. 2006](#); [Schneier et al. 2012](#); [Simon et al. 2008](#)), and there have been no head-to-head trials of CBT and medication monotherapies. Exposure is regarded as the key therapeutic principle in the numerous variants of CBT and is recommended as a first-line treatment for PTSD. Modest preservation of gains is found at long-term follow-up ([Bradley et al. 2005](#)), but much pathology remains.

There has been recent interest in enhancement of exposure therapy by using nonantidepressant drugs that modulate memory through one of the following mechanisms: 1) strengthening fear extinction learning, 2) disrupting memory consolidation, or 3) enhancing engagement in therapy ([Dunlop et al. 2012](#)). Among agents in the first category are D-cycloserine, yohimbine, methylene blue, and hydrocortisone. The second category includes propranolol, mifepristone, and rapamycin. The last category refers specifically to 3,4-methylenedioxymethamphetamine (MDMA), with more than one positive trial of MDMA in facilitation of intensive psychotherapy ([White 2014](#)). At present, the evidence for drug-based enhancement of exposure therapy for PTSD is not clear, and the long-term deleterious effects of such

interventions need to be studied further, but it may be a promising therapeutic approach.

## Acute Stress Disorder and the Immediate Aftermath of Trauma

ASD develops shortly after a traumatic event; it includes symptoms of intrusion, negative mood, dissociation, avoidance, and arousal that persist for at least 3 days and up to 1 month following the trauma and that cause significant distress and/or functional impairment ([American Psychiatric Association 2013](#)). ASD was first included in DSM-IV and further modified in DSM-5, and it has been suggested that early intervention may help to alter the course of PTSD, which would imply early identification and treatment of those with or at risk for ASD.

The effects of open-label treatment with risperidone have been reported in four inpatient survivors of physical trauma with ASD; this drug showed possible benefit in flashback symptoms ([Eidelman et al. 2000](#)).

A controlled pilot study assessed the effects of low-dosage imipramine compared with chloral hydrate in 25 pediatric burn patients with ASD ([Robert et al. 1999a](#)). After 1 week of treatment, 38% of the subjects responded to treatment with placebo, compared with 83% responding to imipramine, and an early report noted reduction in intrusion and hyperarousal symptoms ([Robert et al. 1999b](#)). Unfortunately, a subsequent placebo-controlled trial failed to replicate these promising initial findings ([Robert et al. 2008](#)).

The effects of  $\beta$ -adrenergic blockade in reducing subsequent PTSD following acute trauma were also

evaluated ([Pitman et al. 2002](#)). Within 6 hours of the trauma, subjects were treated with either propranolol ( $n=18$ ; 40 mg four times per day) or placebo ( $n=23$ ) for 10 days, followed by a 9-day taper period. PTSD was noted in 30% of the placebo group compared with 10% of the propranolol group 1 month after the trauma, and at 3-month follow-up, physiological arousal rate to trauma cues was 43% in the placebo group compared with 0% of the propranolol group. However, a follow-up double-blind, randomized controlled 14-day trial of propranolol and gabapentin versus placebo, administered within 48 hours of admission to a surgical trauma unit, did not demonstrate any benefits of the two active drugs over placebo on depressive or PTSD symptoms ([Stein et al. 2007](#)).

A short-term trial with temazepam versus placebo in the acute aftermath of trauma showed no long-term benefits and possibly worse PTSD outcomes at 6-week follow-up ([Mellman et al. 2002](#)).

Three promising studies have found greater long-term benefit for short-term hydrocortisone versus placebo in high-risk subjects recovering from septic shock, cardiac surgery, or acute respiratory distress syndrome ([Hauer et al. 2009](#); [Schelling et al. 2006](#)). In subpopulations with critical illness-related corticosteroid insufficiency, this might be an attractive treatment approach for preventing PTSD. One limitation of the authors' work, however, has been the absence of baseline PTSD ratings before administration of hydrocortisone.

SSRI trials in ASD have been negative so far. [Shalev et al. \(2012\)](#) showed that prolonged exposure therapy and cognitive therapy both initially prevented PTSD in recent trauma survivors with ASD at the 1-month and 5-month follow-ups, whereas escitalopram did not. However, at the

36-month follow-up, the study groups (prolonged exposure, cognitive therapy, escitalopram, placebo, and no intervention) had similar PTSD rates, as measured by the CAPS ([Shalev et al. 2016](#)). Similarly, a double-blind, placebo-controlled 24-week trial in 31 subjects with full or partial ASD showed no difference between escitalopram and placebo ([Suliman et al. 2015](#)).

Treatment with morphine in the immediate aftermath of traumatic injury was associated with lower rates of PTSD in a sample of 696 U.S. military personnel identified through records review ([Holbrook et al. 2010](#)). Morphine may act by inhibiting stress-enhanced fear learning; however, further studies are needed to assess the immediate and long-term effects of this intervention. Shortened forms of CBT appear to be effective for acute PTSD-like states, with persistence of gain at 4-year follow-up ([Bryant et al. 1998, 2003](#)).

---

## Conclusion

---

Twenty years ago, few would have thought that one class of drugs, the SSRIs, all of which were initially introduced for depression, would have established primacy in most major anxiety (or anxiety-related) disorders. Their position is based on numerous placebo-controlled trials, and they are considered first-line drugs for treatment of these disorders, followed closely by the SNRIs. There is evidence that these drugs also offer some protection against relapse. However, they are not 100% successful, they carry some limiting side effects, and they may require supplementation with, or substitution by, drugs from other categories. We have reviewed the main clinical trials of these other drugs and

expect further progress in the pharmacotherapy of anxiety and related disorders, with both established drugs and novel categories. Among many unexplored areas, we need to know more about the treatment of resistant and comorbid anxiety disorders, combined psychotherapy and pharmacotherapy interventions, the comparative efficacy of pharmacotherapy and psychosocial treatments, and possible early interventions that may help prevent and/or alleviate the severity and chronicity of these conditions.

## CHAPTER 49

# Treatment of Schizophrenia

Tsung-Ung W. Woo, M.D., Ph.D.

Carla M. Canuso, M.D.

Joanne D. Wojcik, Ph.D., P.M.H.C.N.S.-B.C.

Douglas Noordsy, M.D.

Mary F. Brunette, M.D.

Alan I. Green, M.D.

**Schizophrenia** is a debilitating brain disorder characterized by a chronic relapsing and remitting course of psychosis that is superimposed on persistent “deficit” features such as cognitive dysfunction and negative symptoms. It appears to be equally prevalent across geographical and cultural boundaries (see [Jablensky et al. 1992](#)), affecting approximately 1% of the population ([Perälä et al. 2007](#)).

Considerable progress has been made in the pharmacological treatment of schizophrenia since the serendipitous discovery in the early 1950s of chlorpromazine as the first effective antipsychotic medication ([Lehmann and Hanrahan 1954](#)). Many other antipsychotic agents, all sharing chlorpromazine’s dopamine D<sub>2</sub> receptor-blocking ability, were subsequently developed. These “conventional,” or first-generation, antipsychotics are all effective in the treatment of positive symptoms of psychosis, but they all have limited beneficial effects on negative symptoms and cognitive deficits.

Since 1990, a second generation of antipsychotic drugs has been available in the United States. These second-generation agents are also commonly referred to as “atypical” or “novel” antipsychotics, largely because of their reduced propensity (compared with the conventional agents) to cause extrapyramidal side effects (EPS). It has been postulated that this unique property (i.e., the low risk of EPS) may reflect the potent serotonin type 2A (5-HT<sub>2A</sub>) receptor antagonistic effects—or, more specifically, the high ratio of 5-HT<sub>2A</sub>-to-D<sub>2</sub> receptor occupancy—of these drugs ([Meltzer 1989](#)). More recently, it has been

proposed that the rapid dissociation (high dissociation constant) of these drugs from D<sub>2</sub> receptors may be another very important pharmacological property that determines “atypicality” ([Kapur and Remington 2001](#); [Seeman 2002](#)).

The focus of schizophrenia treatment has been gradually expanding beyond the targeting of psychotic or positive symptoms of the illness alone. Second-generation agents have been reported by some (but not all) investigators to improve some aspects of negative symptoms and cognitive impairment. Moreover, development of compounds that can improve cognition has become one of the main foci in schizophrenia research ([Barch 2010](#); [Buchanan et al. 2007](#); [Fenton et al. 2003](#); [Hyman and Fenton 2003](#); [Marder 2006](#); [Young and Geyer 2015](#)). In recent years, schizophrenia has been increasingly conceptualized as a neurodevelopmental disorder ([Insel 2010](#)). In this context, the field has developed a focused interest on early diagnosis and early intervention during the prodromal phase before the onset of overt psychosis, in an attempt to improve the overall course or perhaps even prevent the actual onset of overt illness in individuals who appear likely to develop schizophrenia.

---

## Clinical Manifestations of Schizophrenia

---

There is a general consensus, following the seminal work of several investigators (e.g., [Andreasen 1985](#); [Crow 1985](#)), that schizophrenia can be conceptualized as a disorder with at least two more or less orthogonal dimensions of symptomatology: positive and negative symptoms.

### Positive Symptoms

Positive symptoms are perceptual or cognitive features that individuals without psychiatric disorders usually do not experience. They include hallucinations, delusions, and disorganized thinking, although disorganization also can be conceptualized as an independent symptom dimension ([Liddle et al. 1989](#)). As a general rule, positive symptoms tend to respond to treatment with antipsychotic medications. These symptoms do not appear to bear any significant association with or predict the long-term functional outcome of the illness ([Green et al. 2000](#)). It also should be emphasized that psychotic symptoms are not unique to schizophrenia; they can occur in a wide spectrum of other psychiatric, neurological, and medical disorders. Therefore, it is essential to rule out other possible causes of psychosis before a diagnosis of schizophrenia is made.

### Negative Symptoms

Negative symptoms represent a “loss” of functions or abilities that people without schizophrenia normally possess. They include anhedonia, affective flattening, alogia, avolition, and asociality. Negative symptoms are somewhat associated with intellectual and neurocognitive impairment ([Dickerson et al. 1996](#); [Harvey and Keefe 1998](#)), and they are better predictors of long-term functional outcome and psychosocial functioning of schizophrenia patients than are positive symptoms ([Buchanan et al. 1994](#); [Dickerson et al. 1996](#); [Harvey and Keefe 1998](#)). However, neurocognitive deficits in schizophrenia (see subsection with that name later in this chapter) remain the strongest predictors of outcome ([Green 1996](#)). It is important to remember that EPS produced by antipsychotic medications can sometimes resemble negative symptoms of schizophrenia.

The concept of primary versus secondary negative symptoms may provide a useful framework for assessing symptoms ([Carpenter et al. 1988](#)). According to this construct, *primary* negative symptoms represent the core negative symptoms reflecting the schizophrenia disease process. *Secondary* negative symptoms, on the other hand, are caused by or are secondary to positive symptoms of psychosis or the antipsychotic medications themselves. A reduction in medication dosage may alleviate some secondary negative symptoms, but this strategy is unlikely to have a beneficial effect on primary negative symptoms.

---

## Diagnosis of Schizophrenia

---

According to DSM-5 ([American Psychiatric Association 2013](#)), to make the diagnosis of schizophrenia, there must be evidence of continuous symptomatic disturbance for at least 6 months accompanied by a decline from the premorbid level of functioning. Thus, in line with the Kraepelinian concept ([Kraepelin 1919/1971](#)), DSM-5 emphasizes the longitudinal course of deterioration of the illness. This 6-month period can include functional deterioration occurring during the prodromal phase before the onset of overt psychosis. Within the 6-month period, the patient must have experienced two or more of the following symptoms for at least 1 month: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms; and one of these symptoms must be a positive symptom (delusions, hallucinations, or disorganized speech). If the duration of psychotic symptoms is less than 1 month because of successful treatment with antipsychotic medication, a diagnosis of schizophrenia may still be made. In DSM-IV-TR ([American Psychiatric Association 2000](#)), only one of the five symptoms was required if delusions were bizarre or if Schneiderian first-rank auditory hallucinations (i.e., a voice keeping up a running commentary on the person’s behavior or thoughts or two or more voices conversing with each other) were present. However, because of the poor specificity of Schneiderian symptoms and bizarre delusions, this special designation was removed in DSM-5. Another major change in DSM-5 was the

removal of the subtypes of schizophrenia because of their limited reliability and validity.

---

## Neurocognitive Deficits in Schizophrenia

---

Schizophrenia appears to be associated with a decline in general cognitive functions, including verbal declarative memory, working memory, executive function, and attention. There is strong evidence that cognitive deficits predate the onset of psychosis, followed by a significant decline during the early course of the illness ([Aylward et al. 1984](#); [David et al. 1997](#); [Keefe 2014](#), [Nelson et al. 1990](#); [Reichenberg 2010](#); [Russell et al. 1997](#); [Simon et al. 2007](#)). It appears that after this initial decline, the level of cognitive impairment follows a relatively stable course for several decades without evidence of significant further deterioration ([Bozikas and Andreou 2011](#); [Elvevåg and Goldberg 2000](#); [Goldberg et al. 1993](#); [Lewandowski et al. 2011](#)).

---

## Course of Schizophrenia

---

Schizophrenia is a chronic illness, with the onset of psychotic symptoms usually occurring around late adolescence or early adulthood ([Lewis and Lieberman 2000](#)). The age at onset is approximately 5 years later in women than in men ([Angermeyer et al. 1990](#); [Faraone et al. 1994](#); [Hambrecht et al. 1992](#); [Szymanski et al. 1995](#)). Although there may be no clear sex differences in cross-sectional symptomatology of the illness ([Häfner et al. 1993](#); [Szymanski et al. 1995](#)), women in general tend to have more favorable outcomes.

Accumulating evidence suggests that schizophrenia is a neurodevelopmental disorder ([Lewis and Levitt 2002](#); [Murray 1994](#); [Pilowsky et al. 1993](#); [Waddington 1993](#); [Weinberger 1987, 1996](#)). It has been postulated that disturbances in brain development during the first and second trimesters may contribute to the pathophysiology of the illness ([Waddington 1993](#)). Other factors such as obstetrical complications may further alter the course of brain development ([Cannon 1997](#); [Geddes and Lawrie 1995](#)).

For a period of 2–5 years before the onset of the first overt psychotic episode, up to three-quarters of the patients who eventually develop schizophrenia show a wide spectrum of “prodromal” symptoms and reduced functioning ([Docherty et al. 1978](#); [Freedman and Chapman 1973](#); [Häfner et al. 1992, 1993, 1994](#); [Huber et al. 1980](#); [Lieberman 2006](#); [Simon et al. 2007](#); [Varsamis and Adamson 1971](#); [Yung and McGorry 1996a, 1996b](#)). Prodromal symptoms are usually affective or cognitive in nature (e.g., depressed mood, social withdrawal, decreased concentration and attention, decreased motivation, agitation, anxiety, and sleep disturbances) and can also include attenuated positive symptoms.

After the onset of the first episode of psychosis, the course of the illness is often characterized by a gradual deterioration, especially over the first 2–5 years ([McGlashan 1998](#)). Some evidence suggests that functional deterioration may be accompanied by a gradual loss of gray matter volume in the cerebral cortex ([DeLisi et al. 1997](#); [Kasai et al. 2003a, 2003b](#); [Salisbury et al. 2007](#); [van Haren et al. 2008](#); [Zipursky et al. 1992](#)). In fact, increasing evidence suggests that gray matter reduction may have already begun prior to the onset of frank illness ([Moorhead et al. 2013](#); [Pantelis et al. 2003](#); [Takahashi et al. 2009](#); [Witthaus et al. 2009](#)). Although there has been speculation that these observations of functional and structural brain changes around the onset of psychosis may reflect a neurodegenerative process ([DeLisi 1999](#); [DeLisi et al. 1997](#); [Lieberman 1999](#)), the available evidence in support of the neurodegeneration hypothesis of schizophrenia remains weak ([Carpenter 1998](#); [Weinberger and McClure 2002](#)). An alternative interpretation of these findings is that they represent the dysregulation of late developmental processes that involve refinement of brain circuits through pruning of synaptic connectivities ([Sekar et al. 2016](#)).

After an initial period of functional deterioration, symptoms tend to become more or less stabilized. Positive symptoms often respond to treatment, whereas negative symptoms are believed to be relatively treatment resistant and may tend to become increasingly prominent during the course of the illness ([Breier et al. 1991](#)). Most studies ([Ho et al. 2000](#); [Kane et al. 2016](#); [Marshall et al. 2005](#)) have suggested that early intervention during the very first episode of psychosis could be associated with better overall prognosis; thus, a major goal in the treatment of schizophrenia is early recognition and timely treatment of the illness.

---

## Management of Schizophrenia

---

### Acute Psychosis

The acute phase of schizophrenia is characterized by psychotic symptoms and often by agitation. Affective symptoms such as depression and mania also may be present. Patients who are unable to care for themselves or who show a risk of harming themselves or others may require hospitalization. Acute psychosis requires treatment with antipsychotic medication.

Management of an acutely agitated and psychotic patient may require physical restraint and parenterally administered antipsychotic medication. Many physicians still use a high-potency first-generation antipsychotic either alone or in conjunction with a benzodiazepine (such as lorazepam) and/or an anticholinergic drug (such as benztropine) for acute symptom management. Additionally, intramuscular administration of a second-generation antipsychotic, such as olanzapine or ziprasidone, is also increasingly common.

If the patient has a history of treatment with antipsychotic medications, the clinician must ascertain whether the current psychosis is the result of nonadherence to the medication regimen or a “breakthrough” episode due to loss of therapeutic response to the medications. Noncompliance with antipsychotic medications is common and is one of the major causes of symptom exacerbation or full-blown relapse ([Crow et al. 1986](#); [Lieberman et al. 1993](#); [Robinson et al. 1999](#)). Causes of noncompliance vary, but the most common reasons are unpleasant side effects, lack of insight into the illness, delusional interpretations about medication, substance use, and lack of a supportive environment ([Kampman and Lehtinen 1999](#)). With noncompliant patients, it is imperative to focus on improving adherence by providing psychoeducation to the patient (and family, if available), discussing with the patient the reasons for nonadherence, and developing a plan for improved adherence (which may include daily support and monitoring of medication dosages). Depot or long-acting injectable medications also should be considered if noncompliance is a persistent or recurring problem. In the case of apparent breakthrough psychosis, a change in the patient’s medication regimen may be indicated. Other causes of exacerbation of psychosis include comorbid substance use disorders and comorbid depression, as well as psychosocial stressors such as difficulties with housing, employment, benefits, insurance, disability, family, or friends. Therefore, although medications are undoubtedly the mainstay of initial treatment of psychosis, other interventions such as psychotherapy, group therapy, family therapy, dual-diagnosis treatment, social skills training, and case management are important adjuncts to pharmacological management.

## First-Episode Psychosis

Emphasis on the early diagnosis and treatment of the first psychotic episode of schizophrenia arises from evidence suggesting that longer durations of untreated psychosis may be associated with poorer long-term outcomes ([Birchwood 1992](#); [Cechnicki et al. 2014](#); [Harris et al. 2005](#); [Loebel et al. 1992](#); [Marshall et al. 2005](#); [Penttilä et al. 2014](#); [Perkins et al. 2005](#); [Wyatt 1991](#)). Unfortunately, the average time between onset of symptoms and initiation of treatment in the United States is a year and a half ([Addington et al. 2015](#)). Coordinated specialty care provided to patients and their families as early as possible in the course of illness improves outcomes and may reduce disability ([Kane et al. 2016](#)).

Because of their more favorable neurological side-effect profiles (mainly the reduced risks of adverse neurological events such as parkinsonism, akathisia, and tardive dyskinesia), the second-generation antipsychotics are often used in the initial treatment of first-episode psychosis. Because patients are likely to require long-term treatment, clinicians often choose medications with the lowest risk for cardiometabolic side effects (weight gain, hyperlipidemia, and

glucose intolerance), monitor all side effects regularly in accordance with published guidelines ([American Diabetes Association et al. 2004](#)), and adjust medication types and dosages on the basis of efficacy and tolerability. In general, a conservative titration schedule is appropriate for first-episode patients, in part to minimize side effects but also to take into account that these patients may require only low dosages for the control and remission of symptoms ([Remington et al. 1998](#); [Robinson et al. 1999](#); [Schooler et al. 2005](#); [Wyatt 1995](#)).

After remission of an initial episode of psychosis, discontinuation of medication, even if done very gradually, is controversial and often not attempted. Any such decision should be made in light of studies showing that the relapse rate is very high after medication discontinuation in first-episode schizophrenia ([Crow et al. 1986](#); [Johnson 1985](#); [Kane et al. 1982](#); [Robinson et al. 1999](#)). [Gitlin et al. \(2001\)](#), using a low threshold to define recurrence of symptoms, reported that the relapse rate in the first year after medication discontinuation was 78%, and this rate had increased to 98% by the end of the second year.

## Choice of Antipsychotics

Since the early 1990s, second-generation antipsychotics have been used widely. The National Institute of Mental Health (NIMH) sponsored the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study ([Lieberman et al. 2005](#)), which was designed to compare the effectiveness of four second-generation antipsychotics (olanzapine, quetiapine, risperidone, ziprasidone) and a representative first-generation antipsychotic (perphenazine) in “real-world” schizophrenia patients. The primary outcome measure was treatment discontinuation. Of the 1,432 subjects who received at least one dose of medication, 74% discontinued the study medication before 18 months: 64% of the subjects taking olanzapine discontinued, compared with 74%–82% of those taking perphenazine, quetiapine, risperidone, or ziprasidone. More subjects receiving olanzapine discontinued because of weight gain and metabolic effects, whereas more subjects assigned to perphenazine discontinued because of EPS ([Lieberman et al. 2005](#)). Of interest, individuals assigned to olanzapine or risperidone who were continuing with their baseline medication had significantly longer times until discontinuation than did those assigned to switch antipsychotics ([Essock et al. 2006](#)).

Phase II of the CATIE study involved two treatment pathways—efficacy and tolerability—with randomized follow-up medication based on the reason for discontinuation of the previous antipsychotic drug ([McEvoy et al. 2006](#); [Stroup et al. 2006](#)). For patients who failed to improve with an atypical antipsychotic, clozapine was more effective than switching to another atypical antipsychotic ([McEvoy et al. 2006](#)), and in patients who failed to respond to perphenazine,

olanzapine or quetiapine was more effective than risperidone ([Stroup et al. 2006](#)). Moreover, in subjects who discontinued a second-generation agent for tolerability or efficacy reasons but who were unwilling to be randomly assigned to clozapine, risperidone or olanzapine was more effective than quetiapine or ziprasidone ([Stroup et al. 2006](#)). (Note: Since the CATIE study was published, several new antipsychotics—asenapine, brexpiprazole, cariprazine, iloperidone, lurasidone, and paliperidone—have been approved by the U.S. Food and Drug Administration [FDA]. A very limited number of direct comparison studies appear to suggest that these new antipsychotics are neither more nor less efficacious compared with older second-generation antipsychotics ([Fu et al. 2014a, 2014b](#)), but little is known about the effectiveness of these newer agents relative to the older agents.) Finally, although the CATIE cost-effectiveness analysis found perphenazine to be less costly than—and similar in effectiveness (based on quality-adjusted life-years) to—each of the atypical antipsychotics tested, the investigators noted that their results could not be generalized to all patient populations; they therefore concluded that the study findings did not warrant policies that would unconditionally restrict access to a particular medication ([Rosenheck et al. 2006](#)).

Similar to the NIMH-sponsored CATIE study, the United Kingdom's National Health Service funded the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS). This study of 227 schizophrenia-spectrum patients randomly assigned to first- and second-generation antipsychotics (other than clozapine) found no difference between the groups in quality of life, symptoms, or health care costs at 1 year ([Jones et al. 2006](#)).

Neither the CATIE nor the CUtLASS study addressed the comparative effects of oral versus long-acting injectable antipsychotics. Mirror-image studies in which patients served as their own control subjects provide evidence of substantial benefit for first-generation long-acting injectable antipsychotics over oral antipsychotic medications ([Kane et al. 2013](#); [Kishimoto et al. 2014](#); [Schooler 2003](#)), although this putative superiority is in general not supported by findings from randomized controlled trials ([Kishimoto et al. 2014](#); [Rosenheck et al. 2011](#)). At present, risperidone, paliperidone, olanzapine, and aripiprazole are the only second-generation antipsychotics available in long-acting injectable formulations.

Taken together, the CATIE and the CUtLASS studies indicate that antipsychotic medications are generally effective but have a variety of shortcomings. Physicians need to be well informed about the differential tolerability profiles among the antipsychotics. Several of the first-generation agents clearly have a high risk of EPS and tardive dyskinesia ([Glazer 2000b](#); [Jeste et al. 1998](#); [Tollefson et al. 1997](#)). Risperidone and paliperidone tend to elevate serum prolactin levels and may cause EPS at higher dosages. Iloperidone may elevate serum prolactin to a lesser degree. Akathisia and other EPS also may be common with aripiprazole, brexpiprazole, cariprazine, and lurasidone. Although weight gain and metabolic disturbances are associated

with most of the second-generation agents, olanzapine and clozapine appear to have the highest likelihood of causing these side effects ([Allison et al. 1999](#); [American Diabetes Association et al. 2004](#)). Sedation is most commonly observed in patients receiving asenapine, quetiapine, olanzapine, ziprasidone, or clozapine. Ziprasidone, paliperidone, and iloperidone carry product labeling for QTc prolongation and should be used with caution in patients at risk for QTc prolongation. Finally, clozapine, because of its side effects of agranulocytosis, seizures, and myocarditis, is generally reserved for patients with treatment-resistant illness or suicidality. [Table 49-1](#) lists the available formulations for the most commonly used first-generation antipsychotic medications and all of the second-generation agents.

**TABLE 49-1. Antipsychotic medications**

Antipsychotic name	Tablet/capsule	Orally disintegrating	Liquid	Short-acting	Long-acting
		tablets		injection	injection
Commonly used first-generation agents					
Chlorpromazine (low potency)	X		X	X	
Perphenazine (midpotency)	X		X	X	X
Fluphenazine (high potency)	X		X	X	X
Haloperidol (high potency)	X		X	X	X
Second-generation agents					
Aripiprazole	X	X	X	X	X
Asenapine		X			
Brexpiprazole	X				
Cariprazine	X				
Clozapine	X	X			
Iloperidone	X				
Lurasidone	X				
Olanzapine	X	X		X	X
Paliperidone	X				X
Risperidone	X	X	X		X
Ziprasidone	X			X	

# Maintenance Treatment

The major goals of maintenance treatment are prevention of relapse and improvement in psychosocial and vocational functioning. The primary methods used to achieve these goals consist of an integration of optimal psychopharmacological and psychosocial treatments. Treatment and prevention of other psychiatric comorbidities, such as substance use disorders, are important aspects of maintenance treatment. Also, prevention and treatment of medical comorbidities that may be associated with second-generation antipsychotics, as well as those that may result from the lifestyles of some patients with schizophrenia who are given these drugs, have become a very important part of long-term management.

Prevention of relapse improves long-term clinical outcomes ([Wyatt et al. 1998](#)) and reduces the associated economic burden of the illness ([Bernardo et al. 2006](#)). With each relapse, the time required to regain clinical stability lengthens, with the possible consequence of ultimate unresponsiveness to treatment ([Lieberman et al. 1993](#); [Wyatt et al. 1998](#)). Nonadherence to medication is a significant predictor of relapse ([Schooler 2006](#)); long-acting injectable antipsychotics may have the potential to improve medication adherence and thus improve long-term outcomes.

## Treatment-Resistant Schizophrenia

At least 30% of patients with schizophrenia have an incomplete to poor response to antipsychotics, with persistent psychotic symptoms ([Kane et al. 1988, 2007](#); [Tamminga 1999](#)). For research purposes, [Kane et al. \(1988\)](#) operationally defined *treatment resistance* as 1) lack of significant response to at least three adequate trials of antipsychotics from at least two different chemical classes in the past 5 years and 2) persistently poor social and occupational functioning.

Most of the available data suggest that clozapine is the most effective drug for treatment-resistant schizophrenia ([Kane et al. 2001](#); [Lewis et al. 2006](#); [McEvoy et al. 2006](#)). However, because of the serious side effects that may be associated with clozapine and the requirement for frequent white blood cell count monitoring, some patients and some psychiatrists are reluctant to use it, and some patients are unable to tolerate it. Whether the other second-generation agents even approach the effectiveness of clozapine for the treatment of these chronically ill patients is also unclear. Evidence regarding whether either risperidone ([Bondolfi et al. 1998](#); [Breier et al. 1999](#); [Volavka et al. 2002](#)) or olanzapine ([Buchanan et al. 2005](#); [Tollefson et al. 2001](#); [Volavka et al. 2002](#)) is as effective as clozapine is mixed. Other preliminary data also suggest the possible utility of quetiapine, aripiprazole, and ziprasidone in treatment-resistant illness ([Emsley et al. 2000](#); [Kane et al. 2006, 2007](#)).

Multiple controlled trials have assessed whether combining two antipsychotics is more effective than antipsychotic monotherapy. Thus far, the evidence is mixed and inconclusive ([Barbui 2008](#); [Correll et al. 2009](#); [Evins et al. 2005](#)), and many patients taking two antipsychotics are able to switch back to a single agent without destabilization ([Essock et al. 2011](#)). In summary, clozapine remains the primary medication for treatment-resistant schizophrenia, although some studies suggest that other second-generation agents also may have a role in the management of this disorder. Clinically, judicious addition of adjunctive agents, such as mood stabilizers, may be beneficial. Clearly, more research is needed to guide treatment in patients with severe and resistant symptoms.

## Neurocognitive Deficits

Neurocognitive deficits, especially disturbances in executive functioning, memory, and attention ([Green 1996](#); [Green et al. 2000](#)), are closely associated with the long-term functional outcome of patients with schizophrenia. It appears that second-generation antipsychotics may improve some aspects of cognition in schizophrenia, as found in meta-analysis reports ([Bilder et al. 2002](#); [Désaméricq et al. 2014](#); [Woodward et al. 2005](#)). The therapeutic effects of the newer antipsychotics are most notable in measures of verbal fluency and executive functioning, whereas improvement in memory may be more limited. However, data obtained from the CATIE trial showed that at 18 months of treatment, perphenazine was actually more effective than any of the second-generation drugs in improving all domains of neurocognitive deficits ([Keefe et al. 2007](#)). The investigators postulated that several factors might potentially explain this unexpected finding, such as sample size, differences between midpotency drugs such as perphenazine and high-potency drugs (e.g., haloperidol) that were commonly used in prior studies, the real-world features of the CATIE sample, and prior drug trials before entering the study ([Keefe et al. 2007](#)). Interestingly, a meta-analysis of 34 studies found that first-generation antipsychotics do appear to have some cognition-enhancing properties, although effect sizes tend to be quite small ([Mishara and Goldberg 2004](#)). Finally, it is not clear whether any of the apparent statistically significant improvements in neurocognitive deficits measured in the laboratory can actually be translated into improved functional outcomes, for example, in terms of employment, school performance, or social role (see [Green 2002](#)).

---

## Psychosocial Treatment of Schizophrenia

---

Despite the proven efficacy of antipsychotics in the treatment of schizophrenia, most patients continue to have some degree of residual positive symptoms, negative symptoms, and cognitive deficits, and many have difficulty attaining or

regaining their desired level of social and occupational functioning. To address functional goals, treatment is ideally offered by a multidisciplinary team that includes, at a minimum, a medication prescriber and a clinician skilled in psychosocial rehabilitation but also may include employment and housing specialists. Programs that use clinical case managers to directly assist patients in accessing services and to provide the psychosocial interventions are ideal ([Rapp and Goscha 2004](#)). In the first episode of psychosis, specialized programs are tailored for young people and their families to maximize engagement, rapid stabilization, and return to psychosocial functioning ([Mueser et al. 2015](#)). To date, several different types of psychosocial interventions have been empirically shown to reduce rates of relapse and rehospitalization, and a variety of treatments may assist patients in acquiring social and vocational skills and possibly in managing residual psychotic symptoms ([Bustillo et al. 2001](#); [Lauriello et al. 1999](#); [Penn and Mueser 1996](#)). Initial studies have shown that psychosocial treatments can be effective when delivered via technology ([Ben-Zeev et al. 2014](#); [Brunette et al. 2011b](#); [Gottlieb et al. 2013](#); [Rotondi et al. 2010](#)), potentially increasing their reach while maintaining quality and lowering the cost of psychosocial treatment. Importantly, the interaction between pharmacological and psychosocial treatments appears to be more than additive, because each can enhance the effects of the other and affect different domains of outcome ([Marder 2000](#)).

## Relapse Prevention

It has long been noted that patients with highly critical or overinvolved family members (so-called high-expressed-emotion [EE] families) have a higher risk of relapse ([Brown and Rutter 1966](#)). In a classic study, [Goldstein et al. \(1978\)](#) reported that a 6-week therapy focusing on teaching families more effective communication and dispute-resolution skills reduced relapse rates for up to 6 months. Many other studies have since confirmed the efficacy of family psychoeducational interventions (involving education and training in problem-solving techniques and/or cognitive and behavioral management strategies) to prevent relapse and to improve other outcomes ([Falloon et al. 1982](#); [Pilling et al. 2002](#); [Pitschel-Walz et al. 2001](#); [Tarrier et al. 1988](#)). In addition, the positive effect of family interventions seems to persist beyond the time of intervention ([Sellwood et al. 2001](#)) and is independent of either the specific form or the intensity of the intervention ([Bustillo et al. 2001](#)).

Another psychosocial intervention that has been shown to be effective in preventing relapse or rehospitalization in schizophrenia is assertive community treatment (ACT). This intervention, which involves intensive multidisciplinary team management and service delivery in both community and inpatient settings, is designed for individuals who experience intractable symptoms and high levels of functional impairment. At least 30 studies of ACT have shown

advantages over standard community treatment in reducing symptoms, family burden, and hospitalization and in improving independent living, housing stability, and quality of life ([McFarlane et al. 2015](#); [Mueser et al. 1998](#); [Phillips et al. 2001](#); [Stein and Test 1980](#)). However, it appears that the advantages of ACT do not persist after discontinuation of the program, even after prolonged delivery of services.

## Improvement of Psychosocial Functioning

Most patients with schizophrenia have personal goals that involve social and occupational functioning in the community; therefore, psychosocial treatment for patients with schizophrenia targets impairments in these areas. In a 3-year study, [Hogarty et al. \(1997a\)](#) found that weekly individual personal therapy, in which an incremental psychoeducational approach based on the patient's phase of recovery was used, had a significant advantage over supportive therapy, family therapy, and combined treatment in improving social adjustment but not in preventing relapse ([Hogarty et al. 1997b](#)). Interestingly, cognitive-behavioral therapy (CBT) may have a role in the management of persistent psychotic symptoms ([Chadwick et al. 1994](#); [Granholtz et al. 2005](#); [Tarrier et al. 2000](#)). CBT involves the use of techniques such as distraction, cognitive reframing of psychotic beliefs or experiences, and verbal challenge followed by reality testing ([Beck and Rector 2005](#); [Kingdon et al. 2008](#)). Reviews and meta-analyses of CBT for psychosis suggest a positive effect for reducing symptoms ([Mueser et al. 2013](#); [Wykes et al. 2008](#)).

Social skills training (SST) is one treatment strategy to help individuals acquire interpersonal disease management and independent living skills. Reviews of SST ([Bellack and Mueser 1993](#); [Kopelowicz et al. 2006](#)) have described three models of SST: basic model, social problem-solving model, and cognitive remediation model. Within the *basic model*, complex social scenarios are broken down to simpler components, the therapist models correct behaviors, and the patient learns through repeated role-play. The combination of this form of SST with antipsychotic medication appears to be more effective than medication alone in reducing relapse ([Hogarty et al. 1986](#)).

The *social problem-solving model* focuses on impaired information processing, which is thought to cause social skills deficits. This model targets symptom and medication management, recreation, basic conversation, and self-care in educational modules, and it has been shown to be modestly effective in enhancing skills ([Eckman et al. 1992](#); [Liberman et al. 1998](#); [Marder et al. 1996](#)). Interventions that use cueing and support in everyday community interactions by friends or family seem to improve transfer of newly learned social skills to community functioning (e.g., [Glynn et al. 2002](#)).

Finally, the *cognitive remediation model* of SST targets more fundamental cognitive deficits, in areas such as attention, memory, and planning, with the

aim of supporting more complex cognitive processes used in learning social and other skills. Small studies have reported mixed results for more complex cognitive and social skills ([Hodel and Brenner 1994](#); [Spencer et al. 1994](#); [Wykes et al. 1999](#)). An integrated approach to the concomitant training of neurocognitive and social cognitive abilities as well as social skills resulted in long-term improvement in social adjustment ([Hogarty et al. 2006](#); [McGurk et al. 2007](#)). One recent trial reported greater cognitive and functional gains when cognitive remediation was combined with physical exercise ([Malchow et al. 2015](#)).

Work to improve social functioning has focused on social cognition—the capacity to perceive the intentions and dispositions of others ([Penn et al. 2006](#)). A preliminary study of social cognition and interaction training—an intervention offered in 18 weekly sessions that focused on emotion training, figuring out situations, and integrating skills into real life—suggested that this treatment may be a promising approach for improving interpersonal functioning and managing symptoms of psychosis ([Combs et al. 2007](#)).

Illness management and recovery (IMR) is a manualized package of empirically supported approaches (psychoeducation, cognitive-behavioral approaches for medication adherence, relapse prevention planning, SST, and coping skills training) delivered in weekly group or individual sessions that are used with a recovery focus that targets each individual's personal life goals ([Mueser et al. 2006](#)). This combination of approaches results in improved symptoms, better community functioning, and reduced hospital readmission ([Bartholomew and Zechner 2014](#); [McGuire et al. 2014](#)).

Although family psychoeducation, CBT, SST, and IMR may improve symptoms and social functioning, they do not appear to affect employment status. However, more than 14 studies suggest that supported employment programs, which use rapid job searches, on-the-job training, continuous job support, and integration with mental health treatment, are more effective than traditional methods in helping patients obtain competitive employment ([Bond 2004](#); [Kinoshita et al. 2013](#); [Mueser et al. 2013](#)). For young people early in the course of their illness, this effective approach has been expanded to include return to education as well as employment ([Bond et al. 2015](#)).

In addition to employment, the ability to maintain a residence in the community is an important marker of community functioning. Simple provision of access to affordable housing by Section 8 certificates improves housing stability ([Hurlburt et al. 1996b](#)). Supported housing, broadly defined as access to independent housing of the patient's choice (often supported with housing subsidies), that is coupled with access to community mental health and support services improves residential stability and reduces hospitalization ([Rog 2004](#)). ACT for homeless individuals also has been shown to reduce homelessness ([Coldwell and Bender 2007](#)).

Because multiple effective psychosocial interventions exist and are still being developed, the choice of which intervention to apply should depend not only on

therapeutic efficacy but also on each individual's goals and preferences. Patients and their families need to be given information about treatment options and should be engaged in discussions with their treatment providers about how treatments can be useful in the context of an individual's symptoms, comorbidities, needs, and preferences.

---

## Management of Medical Comorbidity

---

### Obesity, Diabetes Mellitus, and Metabolic Syndrome

Medication side effects, as well as lifestyle and disease factors, place patients with schizophrenia at increased risk for developing obesity and metabolic side effects, including glucose intolerance, type 2 diabetes, diabetic ketoacidosis, and hyperlipidemia ([Dixon et al. 2000](#); [Meyer and Koro 2004](#); [Wirshing et al. 2002, 2003](#)). Although clinically significant weight gain occurs in a substantial proportion of patients receiving an antipsychotic medication ([Baptista 1999](#)), a convincing body of evidence indicates that certain atypical antipsychotics cause more weight gain than other agents ([Allison et al. 1999](#); [Lieberman et al. 2005](#); [Wirshing et al. 1999](#)). A large meta-analytic study of atypical and typical antipsychotics ([Wirshing et al. 1999](#)) found a mean weight gain of 9.8 lbs with clozapine, 9.1 lbs with olanzapine, and 4.6 lbs with risperidone, compared with 2.4 lbs with haloperidol, whereas the atypical antipsychotic ziprasidone was associated with a less than 1-lb weight gain. Furthermore, the CATIE study found a greater than 7% weight gain from baseline in 30% of the patients receiving olanzapine, 16% of those receiving quetiapine, 14% of those receiving risperidone, 12% of those receiving perphenazine, and 7% of those receiving ziprasidone ([Lieberman et al. 2005](#)). Compared with risperidone, iloperidone may have a higher risk of weight gain ([Weiden et al. 2008](#)) and asenapine ([Potkin et al. 2007](#)) and lurasidone ([Citrome 2011a, 2011b](#)) may have a lower risk. An antipsychotic's propensity to cause weight gain and other cardiometabolic side effects may be substantially greater in children and young adults who are using an antipsychotic for the first time ([Correll et al. 2009](#); [O'Donoghue et al. 2014](#)).

Diabetes mellitus is estimated to occur two to four times more frequently in patients with schizophrenia compared with the general population ([Dixon et al. 2000](#); [Goff et al. 2005](#); [Henderson et al. 2000](#); [Mukherjee et al. 1996](#); [Wirshing et al. 1998](#)). The risk of diabetes in schizophrenia is likely multifactorial, but accrued evidence clearly indicates that atypical antipsychotics are associated with glucose dysregulation ([Jin et al. 2004](#)). Numerous studies of hyperglycemia, new-onset diabetes mellitus, and diabetic ketoacidosis ([Dixon et](#)

al. 2000; Gianfrancesco et al. 2002; Henderson et al. 2000; Wirshing et al. 2002) led to heightened concern, the issuance of warnings by regulatory authorities and class labeling (Jin et al. 2004), and published consensus guidelines on monitoring for cardiometabolic risk (American Diabetes Association et al. 2004). Some atypical antipsychotics appear to increase risk for diabetes beyond typical agents: clozapine and olanzapine are described as having the greatest risk for diabetes (Kessing et al. 2010; Leslie and Rosenheck 2004; Yood et al. 2009). The risk associated with other antipsychotics is not as clear, although the risk associated with aripiprazole, ziprasidone, and lurasidone is described as being low or not different from the risk associated with typical agents in adults with chronic schizophrenia.

Certain atypical antipsychotics (particularly clozapine, olanzapine, and quetiapine) and low-potency conventional agents have been shown to be associated with hyperlipidemia (Henderson et al. 2000; Meyer and Koro 2004; Osser et al. 1999), whereas ziprasidone and aripiprazole do not appear to carry this adverse effect (Kingsbury et al. 2001; Meyer and Koro 2004). The co-occurrence of atherogenic dyslipidemia with abdominal adiposity, insulin resistance, impaired fasting glucose or overt diabetes mellitus, and hypertension constitutes the cluster of clinical features known as the metabolic syndrome. Baseline data from the CATIE study indicated that more than 40% of subjects had metabolic syndrome, with women carrying greater risk than men (McEvoy et al. 2005). The presence of metabolic syndrome is associated with decreased aerobic fitness and increased functional impairment (Vancampfort et al. 2015).

Controlled studies of metformin have reported benefits for reducing weight gain at initiation of antipsychotic therapy, as well as for achieving weight loss during continuing therapy (Ellinger et al. 2010; Mizuno et al. 2014; Praharaj et al. 2011). Moreover, metformin in combination with lifestyle changes was found to be effective in decreasing cardiometabolic risks (Curtis et al. 2012). Controlled studies of topiramate, reboxetine, and modafinil have also shown beneficial effects on cardiometabolic risk factors, although topiramate treatment was associated with substantial side effects (Ellinger et al. 2010). Orlistat, the non-centrally acting weight-control drug, was not better than placebo in one controlled study (Joffe et al. 2008). A case series (Hamoui et al. 2004) suggested that bariatric surgery was as effective in promoting weight loss in patients with schizophrenia as it is in other populations of obese patients. Centrally acting weight-loss drugs (e.g., diethylpropion, fenproporex, amfepramone) that have the potential to increase the activity of biogenic amines could theoretically exacerbate symptoms of psychosis in this population.

Given the high rates of cardiometabolic disease and early mortality in schizophrenia, all other things being equal, prescribers should strongly consider selecting an antipsychotic with lower risk for cardiometabolic side effects first. Clinicians should use pre- and posttreatment monitoring such as that recommended by the American Diabetes Association-American Psychiatric

Association consensus panel ([American Diabetes Association et al. 2004](#)) and deploy pharmacological and/or behavioral strategies to prevent weight gain. Patients who develop cardiometabolic abnormalities may require a medication switch, monitoring, and management of the new abnormalities with behavioral and pharmacological strategies in collaboration with an internist. Although a medication switch may lower the risk of cardiometabolic abnormalities, a dosage reduction may be helpful in decreasing EPS, agitation, and amenorrhea ([Newcomer et al. 2013](#)).

## Tobacco Use Disorder

The rate of smoking in people with schizophrenia continues to be three to four times that seen in the general population ([McClave et al. 2010](#)). Cigarette smoke causes cardiovascular diseases, diabetes, lung diseases, and cancers and is partially responsible for the excess medical disease burden in schizophrenia. Smoking can complicate the treatment of schizophrenia, because cigarette smoke alters liver enzyme metabolism of some antipsychotics, changing the medication blood levels as patients transition in and out of smoke-free hospital settings ([Desai et al. 2001](#)), and nicotine withdrawal in emergency departments and hospitals can contribute to (treatable) agitation during acute psychosis ([Allen et al. 2011](#)).

Treatment of nicotine addiction appears to be more difficult in the schizophrenia population compared with both the general population and other psychiatric populations ([Covey et al. 1994](#)). Nonetheless, evidence suggests that a multimodality approach that integrates motivation-based treatment ([Brunette et al. 2011b](#); [Steinberg et al. 2004](#)), addiction treatment strategies, and tobacco dependence treatment into mental health settings is beneficial ([Ziedonis et al. 2003](#)). FDA-approved tobacco cessation medications combined with individual or group CBT lead to cessation in up to half of patients who initiate treatment ([Evins et al. 2005, 2014](#); [Ferron et al. 2009](#); [George et al. 2000](#); [Weiner et al. 2001](#); [Williams et al. 2004, 2012](#)). As in the general population, relapse can occur rapidly after short-term treatment is discontinued but can be prevented by continuing treatment for 1 year ([Evins et al. 2014](#)). Patients with schizophrenia who use cessation treatment are able to quit smoking and thereby improve their long-term health without adverse effects on the psychotic illness.

## Extrapyramidal Side Effects

Parkinsonism and acute dystonia are associated with the degree of dopamine D<sub>2</sub> receptor occupancy in the striatum ([Kapur and Remington 1996](#)). Thus, high-potency first-generation antipsychotics such as haloperidol have the greatest propensity (especially at high dosages) to cause these side effects, but many

second-generation agents also may cause EPS in a dose-dependent manner. The CATIE study found that the rate of drug discontinuation due to reported EPS was 8% in the patient group receiving the typical antipsychotic perphenazine, with rates of 4% for ziprasidone, 3% for risperidone and quetiapine, and 2% for olanzapine (Lieberman et al. 2005). Among the second-generation agents, iloperidone, asenapine, aripiprazole, olanzapine, quetiapine, and clozapine do not appear to produce clinically significant parkinsonism or dystonia (Citrome 2011a; Kane et al. 2008; Lieberman et al. 2005; Schoemaker et al. 2010; Stip and Tourjman 2010), whereas lurasidone, risperidone, and paliperidone carry some risk (Leucht et al. 2013).

Akathisia, a disturbing sense of inner restlessness and the inability of the patient to stay still, is associated with seemingly purposeless movements (such as tapping or pacing) that may be noticeable to the examiner. Akathisia occurs less frequently with second-generation than with first-generation medication (Kane et al. 2009) and least often with clozapine, olanzapine, quetiapine, iloperidone, and low-potency first-generation antipsychotic medications (Citrome 2011a; Kane et al. 2008; Lieberman et al. 2005; Schoemaker et al. 2010; Stip and Tourjman 2010). Although lowering the dosage of the antipsychotic is an obvious treatment for akathisia, addition of a  $\beta$ -blocker (e.g., propranolol) is often effective. Anticholinergic drugs and benzodiazepines are generally not that effective but can be tried in patients who do not respond to  $\beta$ -blockers, and anticholinergics also may be useful in patients with coexisting parkinsonism.

Parkinsonism (Osser 1999), characterized by tremor, rigidity, and bradykinesia, can occur early in treatment, usually within the initial weeks or months. Bradykinesia includes generalized slowing of movement and a masklike face (with a loss of facial expression); it may be confused with depression or negative symptoms. One variant of parkinsonism, akinesia, can coexist with bradykinesia (but without tremor or rigidity) and may be associated with symptoms of apathy and fatigue. The “rabbit syndrome” (Casey 1999), occurring after months or years of antipsychotic drug treatment, is also a variant of parkinsonism and is characterized by a perioral and jaw tremor. Anticholinergic medications are the treatment of choice for parkinsonism and usually are effective. Reducing the antipsychotic dosage or switching to an antipsychotic less likely to produce EPS also may be helpful.

Acute dystonia occurs most commonly in young males during the week after initiation of antipsychotics or following an abrupt or rapid dosage increase (Ayd 1961; Barnes and Spence 2000; Remington and Kapur 1996). The dystonia may appear as torticollis, trismus, tongue protrusion, pharyngeal constriction, laryngospasm, blepharospasm, oculogyric crisis, or abnormal contractions of any part of the body. Clinically, in addition to the dystonic muscular contractions that may be immediately noticeable, the patient may complain of tongue thickening, throat tightening, and difficulty speaking or swallowing. Acute treatment with either an anticholinergic agent or an antihistamine is usually

highly effective but may need to be repeated at intervals. Should respiratory difficulty develop, medications may need to be given parenterally.

## Tardive Dyskinesia and Tardive Dystonia

Tardive dyskinesia, which is a syndrome of potentially irreversible involuntary movements, and tardive dystonia, which is characterized by sustained muscle contractions, can gradually emerge after a prolonged period of treatment with antipsychotic medications. Accumulating evidence suggests that the second-generation antipsychotics are less likely to cause these tardive syndromes than are the first-generation drugs (Jeste et al. 1998; Kane et al. 1993; Marder et al. 2002; Margolese et al. 2005; Shirzadi and Ghaemi 2006; Tarsy and Baldessarini 2006; Tollefson et al. 1997). However, because many patients have had exposure to more than one second-generation agent, it is difficult to determine the risk associated with individual agents. It appears that in comparison with the first-generation agents, the second-generation drugs collectively carry one-third to one-twelfth the risk of causing tardive dyskinesia and tardive dystonia (Correll et al. 2004, 2009; Kane 2004; Leucht et al. 2003; Margolese et al. 2005).

The most common form of tardive dyskinesia involves dyskinetic movements of the orofacial and buccolingual musculature, manifesting as grimacing, facial tics, lip smacking, chewing, and wormlike movements of the tongue. Involvement of the neck, axial, and extremity musculature also may occur in the form of choreoathetoid movements, which on rare occasions may involve laryngopharyngeal and respiratory muscles. Tardive dystonia may occur earlier in treatment than tardive dyskinesia and is characterized by slow, sustained twisting movements of the head, neck, trunk, and extremities; blepharospasm, torticollis, facial grimacing, back arching, and hyperextension and rotation of the limbs also may be seen (Simpson 2000).

Risk factors for tardive dyskinesia include older age and female sex (Kane 2004), whereas tardive dystonia is more common in younger patients and males. Other important risk factors for tardive dyskinesia include high medication dosages (Glazer 2000a, 2000c) and the presence of other extrapyramidal syndromes (Kane 2004).

Although no treatment has been demonstrated to be effective for tardive dyskinesia, several management strategies may be clinically useful. Clinicians should screen patients taking antipsychotic medications on a regular basis. If tardive dyskinesia develops, switching from a first-generation to a second-generation drug may be helpful. For those patients who are taking a second-generation agent, a switch to another second-generation drug may be considered. Among the second-generation drugs, evidence suggests that clozapine may reduce symptoms of tardive dyskinesia (Glazer 2000a; Lieberman et al. 1991). Patients with tardive dyskinesia who are taking anticholinergic

medications should discontinue these medications, because they can worsen tardive dyskinesia. Finally, the symptoms of tardive dystonia may be alleviated by reducing the dosages of the antipsychotics, by switching from first-generation to second-generation agents (including clozapine), by using anticholinergics, and/or by administering dopamine-depleting agents, such as reserpine or tetrabenazine ([Simpson 2000](#)).

## Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), which occurs in about 1%-2% of patients receiving typical antipsychotic medication and is potentially fatal in up to 20% of cases (without treatment), has been reported to occur during treatment with both the typical ([Caroff and Mann 1993](#)) and the atypical ([Ananth et al. 2004](#); [S. Hasan and Buckley 1998](#); [Wirshing et al. 2000](#)) antipsychotics. Risk factors include intramuscular injections, rapid escalation to high dosages, dehydration, restraint use, and high temperatures. Catatonia and severe disorganization are clinical symptoms that may be associated with a high risk for NMS ([Berardi et al. 2002](#)). Symptoms of NMS include hyperpyrexia, altered consciousness, muscle rigidity and dystonia, and autonomic nervous system dysfunction, as well as laboratory test results indicating elevated creatine phosphokinase, liver enzymes, and white blood cell count. Early detection and rapid treatment of this medical emergency are crucial and include discontinuation of the antipsychotic, treatment in a medical setting that can support vital functioning, and in some cases the use of a dopamine agonist such as bromocriptine or dantrolene, a muscle relaxant ([Koppel 1998](#); [Susman 2001](#)).

## Hyperprolactinemia

Antipsychotic medications—particularly some of the typical agents, as well as risperidone, paliperidone, and lurasidone—can produce an increase in serum prolactin levels ([Dickson and Glazer 1999](#); [Marder et al. 2004](#)). It is well known that hyperprolactinemia secondary to medical disorders (e.g., pituitary tumor) can produce galactorrhea, hypogonadism, and osteoporosis, all of which have also been reported in patients with schizophrenia ([Abraham et al. 1996](#); [Ghadirian et al. 1982](#); [Riecher-Rössler et al. 1994](#); [Windgassen et al. 1996](#); [Yazigi et al. 1997](#)). Yet the relations between antipsychotic-induced hyperprolactinemia and these conditions, perhaps with the exception of galactorrhea ([Windgassen et al. 1996](#)), remain unclear, with conflicting reports in the literature ([Canuso et al. 2002](#); [Costa et al. 2007](#); [Hummer et al. 2005](#); [Kinon et al. 2006](#); [Kleinberg et al. 1999](#); [O'Keane and Meaney 2005](#)).

Clinicians should ask patients about possible symptoms of hyperprolactinemia. If a patient is symptomatic, prolactin levels should be obtained and medical

causes of hyperprolactinemia ruled out. Prolactin elevation-associated symptoms of galactorrhea or of sexual or menstrual dysfunction may be minimized through a dosage reduction or through a medication change to an atypical antipsychotic with less prolactin-elevating potential ([Canuso et al. 1998](#); [Dickson and Glazer 1999](#)).

---

## Psychiatric Conditions Comorbid With Schizophrenia and Their Treatment

---

### Substance-Related Disorders

Nearly one-half of the patients with schizophrenia are reported to have a lifetime history of an alcohol or a substance use disorder, compared with 16% of the general population ([Regier et al. 1990](#)). Alcohol is the most commonly abused substance in chronically ill patients, followed by cannabis and cocaine ([Selzer and Lieberman 1993](#); [Sevy et al. 1990](#)). As in the general population, men with schizophrenia are more likely to abuse substances than are women ([Mueser et al. 1995](#)).

Comorbid substance use has a deleterious effect on the course of schizophrenia ([Grech et al. 1999](#)); use of even small amounts can produce negative effects ([Drake et al. 2001](#); [D'Souza et al. 2005](#)). Patients with schizophrenia and substance use disorders are at increased risk for infectious diseases such as HIV, hepatitis B, and hepatitis C ([Rosenberg et al. 2001](#)); in addition, alcohol and substance use are associated with clinical worsening, poor functioning, and increased rates of hospitalizations and homelessness ([Dixon et al. 1990](#); [Drake and Mueser 1996](#); [Hurlburt et al. 1996a](#); [Negrete et al. 1986](#); [Soni and Brownlee 1991](#)). In some studies, more than 50% of the first-episode patients were reported to have cannabis use disorder ([Rolfe et al. 1999](#)), which often complicates the diagnosis of a psychotic disorder ([Addington 1999](#)).

Although obtaining information from patients about their use of substances of abuse should be a standard part of a medical history, problematic alcohol or substance use is often underrecognized and undertreated in mental health settings ([Ananth et al. 1989](#)). Because patients often deny use of alcohol and drugs, clinicians also should pursue collateral reports from family members, case managers, and others involved in the delivery of services to patients. Patients with schizophrenia and a comorbid alcohol or substance use disorder require treatment for both disorders ([Bellack and DiClemente 1999](#)), optimally in programs that provide long-term comprehensive services along with integrated mental health and substance abuse treatment, including medication management ([Drake and Mueser 2001](#); [Minkoff 1989](#); [Osher and Kofoed 1989](#)).

Although there is no agreed-on pharmacological treatment approach for patients with schizophrenia and comorbid alcohol or substance use disorders (Green et al. 2007, 2008; Wilkins 1997), some investigators have been interested in the potential role of atypical antipsychotics in reducing substance use in these patients. The atypical antipsychotic that has been studied most in this population is clozapine. Preliminary studies of clozapine have reported promising results for reducing alcohol and drug use (Brunette et al. 2006; Buckley et al. 1999; Drake et al. 2000; Green et al. 2003; Lee et al. 1998; Zimmet et al. 2000). A small randomized trial provided some confirmation of these preliminary studies (Brunette et al. 2011a).

Data concerning the potential effects of other atypical antipsychotics on substance use reduction and relapse prevention are even more preliminary. Findings have been mixed for risperidone (Albanese 2000; Green et al. 2003; Petrakis et al. 2006; Rubio et al. 2006; Smelson et al. 2000), olanzapine (Littrell et al. 2001; Noordsy et al. 2001; Sayers et al. 2005; Smelson et al. 2006), quetiapine (Brown et al. 2003; Potvin et al. 2006), and aripiprazole (Beresford et al. 2005; Brown et al. 2005). No research has assessed the effects of brexpiprazole, cariprazine, ziprasidone, asenapine, iloperidone, or lurasidone on substance craving or use.

Other possible pharmacological options with evidence for efficacy in the treatment of substance use disorders in schizophrenia include the following: 1) disulfiram for co-occurring alcohol use disorder (note that use requires monitoring in patients with schizophrenia) (Kofoed et al. 1986; Mueser et al. 2003; Petrakis et al. 2005); 2) naltrexone for co-occurring alcohol use disorder (Petrakis et al. 2004, 2005); 3) the tricyclic antidepressants desipramine and imipramine for comorbid cocaine use disorder (Siris et al. 1993; Ziedonis et al. 1992); and 4) bupropion, nicotine replacement therapy, and varenicline for tobacco use disorder (Evins et al. 2005; George et al. 2002; Nino-Gomez et al. 2010). Acamprosate, although shown to be effective for alcohol use disorder in placebo-controlled trials, has yet to be studied in patients with schizophrenia.

## Depression

Schizophrenia is often associated with depressive states ranging from dysphoria to major depressive disorder (Blum et al. 2015). The Epidemiologic Catchment Area study suggested that individuals with schizophrenia have a 14-fold greater risk of depression compared with the general population (Fenton 2001). At various times, depression has been viewed as an aspect of schizophrenia (McGlashan and Carpenter 1976; Sax et al. 1996), as a response to psychosis (McGlashan and Carpenter 1976; Sax et al. 1996), or as a state occurring after the cessation of frank psychotic symptoms (Birchwood et al. 2000). The DSM-5 Psychotic Disorders Work Group recommended that depressive symptoms that do not meet full criteria for an episode of major depressive disorder be

considered a component of schizophrenia, and in accordance with this view, depression was included as one of eight Clinician-Rated Dimensions of Psychosis Symptom Severity ([American Psychiatric Association 2013](#); [Malaspina et al. 2013](#)).

Depression in patients with schizophrenia must be differentiated from negative symptoms and EPS; the presence of a core depressed mood and related neurovegetative symptoms should be distinguished from flatness of affect, parkinsonism, and anhedonia ([McGlashan and Carpenter 1976](#)). Depression occurring during an exacerbation of psychosis may remit with treatment of the psychosis ([Birchwood et al. 2000](#); [Koreen et al. 1993](#); [Tollefson et al. 1999](#)). However, postpsychotic depression classically develops after the resolution or improvement of psychotic symptoms (see [Birchwood et al. 2000](#); [Koreen et al. 1993](#)). Dysphoria and demoralization ([Iqbal et al. 2000](#); [Siris 2000a](#)) may occur as patients struggle with illness-related disability ([Bartels and Drake 1988](#)).

Treatment of depression in patients with schizophrenia may include both psychopharmacological and psychosocial components ([A. Hasan et al. 2015](#); [Siris 2000b](#)). Because depression may presage an increase in psychosis, the pharmacological treatment of psychotic symptoms should be optimized. Treatment of depression in acute psychosis may be accomplished through the use of antipsychotic medication alone, especially second-generation antipsychotics ([Banov et al. 1994](#); [Levinson et al. 1999](#); [Marder et al. 1997](#); [Tollefson et al. 1998](#)). However, an episode of major depressive disorder that develops after the remission of psychosis often requires the addition of antidepressants to the medication regimen ([Hogarty et al. 1995](#); [Kirli and Caliskan 1998](#); [Levinson et al. 1999](#); [Siris et al. 1987](#)). Psychosocial interventions can help with demoralization and dysphoria ([Siris 2000b](#)). Severe depression also may be treated with electroconvulsive therapy (ECT; [Pompili et al. 2013](#)).

## Suicide

Suicide is one of the leading causes of premature death in patients with schizophrenia, who have a 10% lifetime risk of suicide. Nearly 50% of the patients with schizophrenia attempt suicide during their lifetime ([Black et al. 1985](#); [Tsuang et al. 1999](#)). Risk factors include depression and the diagnosis of schizoaffective disorder ([Harkavy-Friedman et al. 2004](#); [Radomsky et al. 1999](#)), social isolation ([Drake et al. 1986](#); [Goldstein et al. 2006](#); [Potkin et al. 2003](#)), and feelings of hopelessness and disappointment over failure to meet high self-expectations ([Kim et al. 2003](#); [Westermeyer et al. 1991](#)). Patients with a higher level of insight and awareness of their illness may be at increased risk ([Amador et al. 1996](#); [Bourgeois et al. 2004](#); [Crumlish et al. 2005](#)), as may patients with a low level of functioning ([Kaplan and Harrow 1996](#)).

A history of suicide attempts is one of the strongest predictors of suicide in patients with schizophrenia (Potkin et al. 2003; Rossau and Mortensen 1997; Roy 1982). A meta-analysis of 29 case-control and cohort studies indicated that suicide risk factors included previous depressive disorders, substance use disorders, agitation or motor restlessness, fear of mental disintegration, poor adherence to treatment, and recent loss (Hawton et al. 2005).

An increased risk of suicide is present in the early phase of the illness (Drake et al. 1985; Kuo et al. 2005; Nordentoft et al. 2015). Suicide risk peaks immediately after admission and shortly after discharge (Qin and Nordentoft 2005; Rossau and Mortensen 1997). Patients in an active phase of the illness (Heilä et al. 1997) or with positive symptoms (Kelly et al. 2004) may be at particular risk, especially if they have prominent symptoms of suspiciousness and delusions (Fenton et al. 1997).

The treating clinician should regularly evaluate the patient's condition, assess for suicide risk factors, and aim to enhance protective factors such as social support and positive coping skills (Montross et al. 2005). Patients who present with suicidal thoughts or behavior require close follow-up and intensive outreach (Drake et al. 1986; Harkavy-Friedman and Nelson 1997). Improved ward safety, effective substance use disorder therapy, treatment of mood symptoms, and ensured medication adherence are all measures that may help prevent suicide (Hawton et al. 2005; Hunt et al. 2006).

Psychopharmacological treatment plays a crucial role in the prevention of suicide. In one study, more than half of the patients who committed suicide either were noncompliant with their medication regimens or had been prescribed inadequate dosages of antipsychotics, and 23% were estimated to be nonresponsive to their medication (Heilä et al. 1999). Moreover, a landmark study of nearly 1,000 patients with schizophrenia and schizoaffective disorder who were at risk for suicide (but who were not necessarily classically treatment resistant) indicated that treatment with clozapine was more likely to decrease suicidality than was treatment with olanzapine (Meltzer et al. 2003). ECT also may be helpful for suicidal symptoms among people with schizophrenia (Pompili et al. 2013).

## Obsessive-Compulsive Symptoms

Obsessive-compulsive symptoms are seen in 9%-30% of patients with schizophrenia (Berman et al. 1995a; Byerly et al. 2005; Cassano et al. 1998; Ongür and Goff 2005). Although obsessive-compulsive symptoms may be difficult to distinguish from delusions (Eisen et al. 1997), they are important to identify because they may indicate a poor prognosis yet may be responsive to specialized treatment regimens (Byerly et al. 2005; Fenton and McGlashan 1986; Hwang et al. 2000; Ongür and Goff 2005). The obsessive-compulsive symptoms in schizophrenia are similar to those in obsessive-compulsive disorder

([Tibbo et al. 2000](#)), although the symptoms may not be ego-dystonic in patients with schizophrenia.

Treatment of obsessive-compulsive schizophrenia may require the addition of a serotonergic antidepressant to the antipsychotic regimen ([Berman et al. 1995b](#); [Chang and Berman 1999](#); [Poyurovsky et al. 2000](#)). However, prescribers should be mindful of the risk of drug interactions, because the combined use of serotonin reuptake inhibitors with some antipsychotics, particularly clozapine, may lead to excessive antipsychotic serum levels. CBT also may be useful for managing obsessive-compulsive symptoms ([Hagen et al. 2014](#)).

---

## Future Directions

---

Despite advances in understanding of the neurobiology of schizophrenia, and a variety of novel-mechanism agents currently being evaluated in clinical trials, it remains the case that all approved antipsychotic medications primarily modulate the dopamine system. Although postsynaptic dopamine D<sub>2</sub> antagonists and partial D<sub>2</sub> agonists have proven antipsychotic efficacy, these agents are mostly prescribed in oral formulations. Because inconsistent patient adherence can limit the utility of these agents in clinical practice, several longer-acting injectable formulations of existing dopaminergic agents have been developed. These agents traditionally have been dosed every 2–4 weeks, but a 3-month formulation of paliperidone was recently approved, and a 6-week formulation of aripiprazole is available. In earlier stages of drug development are several novel and established dopamine-modulating agents with combined pharmacological activity at other important neurotransmitter receptors, including serotonin, glutamate,  $\sigma_2$ , and the  $\mu$  opioid receptor. Such agents may confer some efficacy or safety benefit over existing medications.

Although dopaminergic drugs will continue to play a major role in treatment of the positive symptoms of schizophrenia, more effective treatments are needed against the functionally disabling negative and neurocognitive symptoms of the illness. Recent drug development efforts, particularly for negative symptoms, have targeted the glutamatergic system. Although promising Phase II findings were reported for a metabotropic glutamate 2/3 receptor agonist ([Patil et al. 2007](#)) and a glycine transport reuptake inhibitor ([Umbricht et al. 2014](#)), later-phase programs yielded disappointing results ([Downing et al. 2014](#); [Kinon et al. 2011](#); [Roche 2014](#)). Several  $\alpha_7$ -nicotinic receptor agonists also have been studied in the treatment of cognitive impairment in schizophrenia. Other novel-mechanism agents that are either under investigation or of theoretical interest for the treatment of cognitive impairment in schizophrenia include  $\alpha_2$   $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor agonists ([Lewis and Gonzalez-Burgos 2006](#)), muscarinic agonists ([Shekhar et al. 2008](#)), serotonin 5-HT<sub>6</sub> ([Roth et al. 2004](#)) and 5-HT<sub>7</sub> ([Horiguchi](#)

et al. 2011; Horisawa et al. 2011; Nikiforuk et al. 2013) receptor antagonists, and phosphodiesterase 10A inhibitors (Kehler and Nielsen 2011).

In addition to recent pharmacological advances in the treatment of schizophrenia, emerging evidence suggests that novel psychosocial approaches, including computerized cognitive remediation, may be of benefit in treating cognitive impairment in schizophrenia (Fisher et al. 2009; Lindenmayer et al. 2008, 2013). Moreover, the use of pro-cognitive medications along with software targeted to engage specific neuronal circuits could facilitate use-dependent plasticity. Such combined therapies, along with social and vocational skills training, could lead to better outcomes in the functioning and quality of life for people with schizophrenia.

The future is also likely to see further progress in the development of treatments for prodromal schizophrenia, with the goal of improving symptoms and delaying or preventing conversion to the full expression of the illness. Interestingly, the risk-benefit ratio of antipsychotic therapy does not appear to be particularly favorable in this population, with studies showing inconsistent benefit in preventing conversion to psychosis and high side-effect burden (McGlashan et al. 2006; McGorry et al. 2002; Yung et al. 2011). Alternatively, promising data from studies of long-chain omega-3 fatty acids (Amminger et al. 2010) and CBT (Morrison et al. 2004) have been reported. Taken together, these results suggest that the therapeutic targets for preventing the progression to schizophrenia differ from the target for treating psychosis. It is hoped that as new treatments for the negative and cognitive systems of schizophrenia emerge, these therapeutics will also be found to have a role in the treatment of prodromal symptoms and the prevention of schizophrenia.

## CHAPTER 50

# Treatment of Substance-Related Disorders

Brian J. Sherman, Ph.D.

Karen J. Hartwell, M.D.

Aimee L. McRae-Clark, Pharm.D.

Kathleen T. Brady, M.D., Ph.D.

Substance use disorders are common in the United States, with data from 2014 indicating that approximately 27 million individuals reported illicit drug use in the past month, 17 million had an alcohol use disorder, and 55.2 million were current cigarette smokers ([Center for Behavioral Health Statistics and Quality 2015](#)). Therefore, many Americans are directly affected by substance use disorders, and millions more are affected through family or friends or through the societal costs associated with substance use disorders. The cost to society is great, exacting more than \$700 billion annually in costs

related to crime, lost productivity, and health care ([U.S. Department of Health and Human Services 2014](#)).

Fortunately, there have been major advances in psychotherapeutic and pharmacotherapeutic treatments for substance use disorders. Recent advances in neurobiology have helped to identify major brain circuitry and neurotransmitter systems involved in substance-related disorders, allowing for the development of treatments that more specifically target systems and regions involved in addictive processes. Unfortunately, in spite of new developments in medication treatments, medications are often underused in the treatment of substance use disorders. For example, even though three medications have been approved by the U.S. Food and Drug Administration (FDA) for relapse prevention in DSM-IV ([American Psychiatric Association 1994](#)) alcohol dependence, a study conducted in the Veterans Administration Medical Center (VAMC) system in 2008–2009 found that only 3.4% of the individuals treated for alcohol dependence were prescribed a medication targeting relapse prevention ([Harris et al. 2012](#)). There are many potential reasons for this, including the fact that much of the addiction treatment system has “grown up” outside of traditional medicine, so medications are sometimes not considered in treatment planning. In addition, many treatment programs still do not have the necessary medical personnel to evaluate patients for appropriateness of medication treatment and prescribe as needed. Many insurance plans provide little coverage for medications to treat substance use disorders. However, the Harris et al. study took place in a VAMC, where cost and access to medical personnel should not have been an issue. Broader education of physicians concerning recognition

and pharmacological treatment of substance use disorders is clearly needed.

In this chapter we focus on pharmacotherapeutic treatments for substance-related disorders, but important advances also have been made in psychotherapeutic and behavioral treatments for these disorders. Although pharmacotherapeutic treatments are an important and sometimes neglected part of the treatment armamentarium, medications alone are rarely sufficient for the treatment of substance use disorders and should be accompanied by comprehensive treatment planning and psychosocial treatment.

A meta-analysis of 34 well-controlled trials of psychosocial therapies included studies of contingency management, relapse prevention, cognitive-behavioral therapy (CBT), and combinations of CBT and contingency management. Contingency management treatments had the lowest dropout rates, at fewer than 30%, followed by CBT and combined psychosocial treatments. Treatment involving relapse prevention techniques led to the highest rate of abstinence, at 39%, and greater time in treatment was related to positive outcomes ([Dutra et al. 2008](#)). Another study found that CBT, 12-step facilitation, and brief motivational therapy were all efficacious in the treatment of DSM-IV alcohol dependence ([Project MATCH Research Group 1997](#)). In addition, substance-related disorders are truly complex disorders that are influenced by biological and psychological factors as well as environmental circumstances. One study comparing standard methadone services with methadone services enhanced by on-site access to medical-psychiatric, employment, and family therapy found that individuals receiving enhanced services

showed significantly better outcomes across several functional domains ([McLellan et al. 1993](#)).

---

## Alcohol-Related Disorders

---

In the United States in 2014, approximately 139.7 million people ages 12 years and older reported past-month alcohol use, and 17.0 million people met criteria for alcohol use disorder ([Center for Behavioral Health Statistics and Quality 2015](#)). From 2006 to 2010, excessive alcohol consumption was responsible for 1 in 10 deaths annually among working-age adults ([Stahre et al. 2014](#)), yet only a fraction (1.4 million in 2013) received any formal treatment ([Substance Abuse and Mental Health Services Administration 2014](#)).

Pharmacotherapy for alcohol use disorder involves a two-stage approach. Detoxification from alcohol is the first step and can be inpatient or outpatient, depending on the severity of dependence and other risk factors such as chronic medical conditions. Following detoxification, pharmacotherapeutic agents may be used to prevent relapse or reduce alcohol intake by targeting different neurotransmitter systems associated with alcohol dependence. The FDA has approved disulfiram, naltrexone, and acamprosate for the treatment of alcohol use disorder.

## Alcohol Withdrawal and Detoxification

Alcohol withdrawal syndrome occurs in approximately 50% of alcohol-dependent individuals on reduction or abstinence following a period of prolonged or heavy alcohol use ([Kosten and O'Connor 2003](#)). Most people presenting with alcohol withdrawal syndrome experience mild symptoms, which may include hand tremor, anxiety, headache, insomnia, nausea or vomiting, diaphoresis, and irritability and can be treated on an outpatient basis. However, approximately 5% experience severe symptoms, including seizures and delirium tremens (DTs), which can be fatal and must be treated on an inpatient basis ([Schuckit 1991, 2014](#)).

Benzodiazepines remain the gold standard for treating alcohol withdrawal ([Mayo-Smith 1997](#); [Schmidt et al. 2016](#)). Benzodiazepines exert sedative, hypnotic, and anticonvulsant effects through positive modulation of the  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor, reducing central nervous system (CNS) hyperactivity associated with alcohol withdrawal ([Brunton et al. 2011](#)). They have been shown to reduce withdrawal severity, seizures, and DTs ([Mayo-Smith 1997](#)). Diazepam and chlordiazepoxide are commonly used and a good choice because of their long half-life, which reduces the risk of rebound symptoms (i.e., seizures) that generally occur a few days into withdrawal. However, they are contraindicated in patients with hepatic or renal dysfunction, the elderly, and/or those at high risk of medical complications associated with the presence of active metabolites and renal excretion. Lorazepam and oxazepam are optimal in such cases, but their short half-life increases the risk for rebound symptoms and requires carefully monitored tapering.

The three most commonly used benzodiazepine detoxification regimens are the symptom-triggered, the

fixed-tapering-dose, and the loading-dose regimens. The symptom-triggered regimen requires frequent clinical assessment with the Clinical Institute Withdrawal Assessment for Alcohol, Revised (CIWA-Ar; [Sullivan et al. 1989](#)) and is most often used in the hospital setting. Dosing is based on CIWA-Ar scores, which can range from 0 to 67 (a score of 20 or greater indicates severe withdrawal). This regimen is advantageous because it involves a relatively short duration of treatment and a smaller total quantity of administered medication ([Daepfen et al. 2002](#)). The fixed-tapering-dose regimen involves administering benzodiazepines at scheduled intervals, with initial dosing determined by symptom severity at presentation. This method is often preferred for outpatient detoxification when frequent assessment and monitoring are impractical. The loading dose regimen involves administering a larger dose of a long-acting benzodiazepine every 2 hours under close monitoring. In all regimens, taper occurs over 5–7 days, depending on initial severity, withdrawal history, and other potential medical complications.

Anticonvulsant medications have shown efficacy in treating mild to moderate withdrawal symptoms or as an adjunct to benzodiazepine pharmacotherapy for more severe withdrawal. Evidence suggests that gabapentin and carbamazepine are the most effective agents and carry additional advantages including absence of abuse liability, reduced probability of rebound seizures, and reduced cravings (for a review, see [Hammond et al. 2015](#)). With any detoxification regimen, vitamin and electrolyte replenishment is an important component.

## Relapse Prevention

## Alcohol-Sensitizing Agents

**Disulfiram.** In 1951, disulfiram became the first medication to be approved by the FDA for alcohol use disorder. Disulfiram inhibits the enzyme aldehyde dehydrogenase, resulting in excess blood levels of the toxic metabolite acetaldehyde. Excess acetaldehyde produces a reaction that may include flushing, nausea, tachycardia, and hypotension. The behavioral pairing of this reaction with alcohol consumption acts as a deterrent for individuals with alcohol use disorder. The reaction can last from 30 minutes to several hours, depending on the dose of disulfiram and the amount of alcohol consumed, and severe reactions may require hospitalization. Because side effects may include hepatic dysfunction, liver function tests should be conducted prior to initiation and subsequently as indicated. The initial dosage and standard maintenance dosage is 250 mg/day, but dosing may range from 125 to 500 mg/day.

Evidence on the efficacy of disulfiram is limited and controversial. The largest placebo-controlled study to date, the Veterans Administration (VA) Cooperative Study of Disulfiram Treatment of Alcoholism ([Fuller et al. 1986](#)), found no group differences in abstinence rates or time to first drink; however, the adherence rate in individuals receiving disulfiram was only 20%. Among more recent studies, some have shown disulfiram to be associated with higher abstinence rates and longer times to relapse ([De Sousa and De Sousa 2004, 2005](#)), whereas others have found no significant effects of disulfiram on drinking outcomes ([Ulrichsen et al. 2010](#)).

An important meta-analysis by [Skinner et al. \(2014\)](#) compared blinded with unblinded clinical trials involving

disulfiram and found it to be efficacious only in the unblinded studies, suggesting that its efficacy may depend on the psychological expectancy of an aversive reaction. Subgroup analysis (unblinded randomized controlled trials [RCTs] only) determined that disulfiram was superior to naltrexone, acamprosate, and placebo. Because of low adherence rates ([Fuller and Gordis 2004](#)), guidelines strongly recommend supervised administration, which results in significantly greater efficacy compared with unsupervised administration ([Skinner et al. 2014](#)).

In summary, disulfiram is efficacious and safe under the proper circumstances. It is recommended for patients who are highly motivated to maintain abstinence, have available supervision, comprehend the consequences of drinking while taking disulfiram, and are medically appropriate ([Substance Abuse and Mental Health Services Administration 2015](#)).

## Opioid Antagonists

**Naltrexone.** The opioid antagonist naltrexone was approved in 1994 for the treatment of alcohol use disorder. Although naltrexone's exact mechanism of action in reducing alcohol use is unknown, preclinical trials suggest that it reduces craving by modulating dopamine activity in the nucleus accumbens and ventral tegmental area and by blocking the effects of endogenous opioids following consumption of alcohol (for a review, see [Johnson 2008](#)).

*Oral naltrexone.* Oral naltrexone has shown significant, although modest, efficacy in improving alcohol outcomes. Early clinical trials found reductions in relapse rates over 12 weeks among participants randomly assigned to

naltrexone 50 mg compared with placebo ([O'Malley et al. 1992](#); [Volpicelli et al. 1992](#)). However, 5 months posttreatment, relapse rates did not differ from those with placebo. Similarly, [Anton et al. \(2001, 2006\)](#) found gradually increasing rates of relapse, number of drinking days, and number of heavy drinking days following termination of up to 16 weeks of naltrexone. The VA Cooperative Study ([Krystal et al. 2001](#)) compared oral naltrexone with placebo over treatment periods of 12 and 52 weeks and found no group differences. However, a systematic Cochrane review of 50 RCTs found a 17% reduction in risk for heavy drinking among participants taking naltrexone compared with placebo ([Rösner et al. 2010](#)).

Poor medication adherence has been problematic and limits the efficacy of naltrexone. [Volpicelli et al. \(1997\)](#) found naltrexone to be superior to placebo only when adherence rates were higher than 90%. One large multisite trial (Combined Pharmacotherapies and Behavioral Interventions for Alcohol Dependence [COMBINE] study;  $N=1,383$ ) sought to address poor adherence by adding a medication management component ([Anton et al. 2006](#)). The adherence rate was 85%, and compared with placebo, participants receiving naltrexone plus medication management showed a significantly reduced risk for heavy drinking.

Some studies suggest that a variant of the gene encoding the  $\mu$  opioid receptor (*OPRM1*) is associated with greater naltrexone efficacy ([Anton et al. 2008](#); [Oslin et al. 2003](#)), but other studies have found no difference in naltrexone efficacy among participants with any *OPRM1* variants ([Gelernter et al. 2007](#)). Clinical characteristics including family history of alcohol use disorder and strong alcohol craving on presentation have been associated with good

clinical response to naltrexone ([King et al. 2002](#); [Monterosso et al. 2001](#)).

*Extended-release injectable naltrexone.* Extended-release injectable naltrexone (XR-NTX) was developed to address problems with adherence and was approved by the FDA in 2006. Depot naltrexone 380 mg can provide protective blood plasma levels for up to 30 days, thus eliminating the need for daily oral administration. The seminal trial of depot naltrexone compared six monthly doses of naltrexone 380 mg, naltrexone 190 mg, and placebo in 600 alcohol-dependent individuals ([Garbutt et al. 2005](#)). The 380-mg group showed the greatest reduction in the number of heavy drinking days compared with placebo. Of note, a treatment effect of depot naltrexone was found only in males. In addition, the dropout rate of 14.1% in the high-dose group was comparable to that in studies of oral naltrexone. In summary, depot naltrexone appears to be effective in reducing heavy drinking days for men, but not for women, and its effect on adherence appears to be limited.

**Nalmefene.** Nalmefene, another opioid antagonist, also has been examined in the treatment of alcohol use disorder. In initial trials, [Mason et al. \(1994, 1999\)](#) found nalmefene to be efficacious in preventing relapse to heavy drinking. However, a later 12-week trial of recently abstinent individuals with alcohol use disorder found no differences between nalmefene and placebo on number of heavy drinking days ([Anton et al. 2004](#)). Recent multisite placebo-controlled trials in Europe have found significant reductions in number of heavy drinking days per month and total alcohol consumption with nalmefene (18 mg) compared

with placebo ([Gual et al. 2013](#); [Mann et al. 2013a](#); [van den Brink et al. 2014](#)).

## Anticraving Agents

**Acamprosate.** Acamprosate, an *N*-methyl-D-aspartate receptor modulator, was approved by the FDA in 2004 for the treatment of alcohol use disorder. Although its exact mechanism of action is unclear, acamprosate appears to reduce craving by promoting a balance between inhibitory (GABA) and excitatory (glutamate) neurotransmitters ([Mason and Heyser 2010](#)). Acamprosate offers some advantages over the other two FDA-approved medications for alcohol use disorder (disulfiram and naltrexone), because it is not metabolized by the liver and therefore not affected by alcohol consumption.

A systematic Cochrane review evaluated the efficacy of acamprosate in 24 randomized, double-blind, controlled trials of 6,894 individuals with alcohol use disorder ([Rösner et al. 2010](#)). Compared with placebo, acamprosate reduced the relapse risk by 14% and increased the cumulative abstinence duration by 11%. Secondary outcomes of return to heavy drinking and  $\gamma$ -glutamyltransferase (GGT) levels did not differ by group. The large randomized, placebo-controlled multisite COMBINE study ([Anton et al. 2006](#)) did not find acamprosate to be superior to placebo on alcohol outcomes, and other large-scale RCTs have reported similar nonsignificant results ([Mann et al. 2013b](#); [Mason et al. 2006](#); [Morley et al. 2006](#)). Acamprosate has shown inferiority to disulfiram and naltrexone on drinking outcomes in open-label clinical trials ([De Sousa and De Sousa 2005](#); [Laaksonen et al. 2008](#)). Some studies have suggested that response to acamprosate may be influenced

by genetic factors, including interactions with GATA binding protein 4 (*GATA4*; [Kiefer et al. 2011](#)) and polymorphisms of the GABA<sub>A</sub> receptor  $\alpha_6$  subunit (*GABRA6*) and D<sub>2</sub> dopamine receptor *DRD2* genotypes ([Ooteman et al. 2009](#)), although replication of these findings is needed.

## Anticonvulsants

**Topiramate.** Several anticonvulsant medications have been investigated for off-label use in treating alcohol use disorder, and topiramate appears the most promising. The mechanism of action in regard to alcohol use is unclear, but it may reduce craving as a result of neurobiological action on GABAergic and glutamatergic signaling in corticomesolimbic regions. [Johnson et al. \(2003\)](#) first examined topiramate 300 mg/day compared with placebo among 150 alcohol-dependent participants and found significant reductions in self-reported alcohol consumption and GGT levels with topiramate compared with placebo. A subsequent multisite trial ( $N=371$ ) found flexible dosing with topiramate (up to 300 mg/day) efficacious in reducing alcohol consumption and GGT levels over the 14-week study period ([Johnson et al. 2007](#)). Numerous adverse side effects were reported in the larger trial, including cognitive impairment (memory, concentration), paresthesias, taste disturbances, and anorexia.

Topiramate has shown mixed results compared with other medications approved for the treatment of alcohol use disorder. Topiramate fared worse than disulfiram, engendering shorter time to relapse ([De Sousa et al. 2008](#)), but showed noninferiority ([Baltieri et al. 2008](#)) and superiority on drinking outcomes, including reduced craving, when compared with naltrexone ([Flórez et al.](#)

2011). Although topiramate can be an effective treatment for alcohol use disorder, poor tolerability may limit its utility.

## Serotonergic Agents

**Ondansetron.** Ondansetron, a serotonin type 3 (5-HT<sub>3</sub>) receptor antagonist, has shown promise in the treatment of alcohol use disorder. An RCT in 71 males with nonsevere alcohol dependency found that low-dose ondansetron (0.25 mg twice a day) was associated with greater reductions in drinking compared with placebo or high-dose ondansetron (2.0 mg twice a day) among participants drinking fewer than 10 drinks per drinking day ([Sellers et al. 1994](#)). The first large-scale RCT ([Johnson et al. 2000](#)) found that for adults with early-onset alcohol use disorder (prior to age 25 years), ondansetron 4 µg/kg twice a day was associated with greater percentages of days abstinent and total days abstinent compared with placebo. Investigations of the clinical utility of ondansetron and other serotonergic agents are ongoing.

---

## Opioid-Related Disorders

---

Opioid use disorder is a serious and increasing public health concern. In the United States in 2014, approximately 2.5 million people ages 12 years and older had an opioid use disorder in the past year ([Center for Behavioral Health Statistics and Quality 2015](#)). Opioids (primarily prescription pain relievers and heroin) were involved in 28,647 deaths in 2014, and the rate of opioid overdose has tripled since 2000 ([Rudd et al. 2016](#)). Opioid use has been associated

with mortality, criminality, violence, HIV, hepatitis C, and poor quality of life ([Hulse et al. 1999](#))

The FDA has approved three medications for the treatment of opioid use disorder: methadone, buprenorphine, and naltrexone. All three agents bind to  $\mu$  opioid receptors, but they differ in their pharmacokinetic and pharmacodynamic properties, intrinsic activity at the receptor, and mechanism of relapse prevention. Of importance, most studies have been conducted in individuals who are primarily intravenous heroin users rather than individuals who use prescription opioids. There may be important differences between these two groups, and more systematic treatment studies of individuals with prescription opioid use disorders are needed.

## FDA-Approved Medications

### **Methadone**

Methadone is a full opioid agonist with high affinity for the  $\mu$  opioid receptor, a long terminal half-life, and delayed steady-state efficacy, which contributes to its risk of fatal overdose during induction. Initial dosing should begin with 10–20 mg. If withdrawal symptoms are not adequately suppressed within 1 hour, additional medication may be required but should not exceed 30 mg in the first day and 40 mg in the first 3 days. Once withdrawal symptoms are stabilized, dosing can be increased to 100 mg or higher for tolerant individuals.

With appropriate administration and adherence, methadone is generally safe. However, methadone-associated risks of respiratory depression, QTc interval prolongation, and sudden death require acute monitoring

and led to a 2006 physician safety alert from the FDA. Methadone may be used for detoxification or maintenance therapy.

## **Buprenorphine**

Buprenorphine is a partial opioid agonist with high affinity for the  $\mu$  opioid receptor and slow dissociation, enabling protection for more than 24 hours in many cases. Given its high affinity and slow dissociation, buprenorphine may induce acute withdrawal if receptors are bound by a full agonist at the time of administration. To avoid precipitating withdrawal, physicians should wait until the patient is experiencing withdrawal symptoms to begin induction. Initial dosing usually begins with 2–4 mg, which, if well tolerated, can be followed by an additional 2–4 mg approximately 8 hours later. Some patients will require a 24- to 32-mg maintenance dose, but most patients can be adequately maintained with 16 mg or less once stabilized.

As a partial opioid receptor agonist, buprenorphine confers a ceiling effect, thus reducing overdose potential and euphoria from illicit opioid use. The safety profile of buprenorphine is therefore more favorable than that of full agonists, and it is not associated with QTc interval prolongation, respiratory depression, or other drug interactions. Buprenorphine may be used for detoxification or in combination with naloxone (discussed further in the “Buprenorphine–Naloxone” subsection later in this chapter) for maintenance therapy.

## **Naltrexone**

Naltrexone is an opioid receptor antagonist with high affinity for the  $\mu$  opioid receptor. Through competitive

antagonism at the  $\mu$  opioid receptor, naltrexone blocks the euphoric effects of opioids and reduces overdose risk. Naltrexone is long acting and may be given every 2–3 days; however, daily administration is recommended. Naltrexone is most effective in highly motivated individuals, because noncompliance is common, and relapse to previous levels of opioid use is potentially fatal for individuals who have lost opioid tolerance while taking naltrexone.

Naltrexone may be used for relapse prevention once abstinence is achieved. Extended-release depot and implant formulations have been developed to improve adherence; these formulations are discussed in the “Extended-Release Injectable Naltrexone” subsection under “Relapse Prevention” later in this chapter.

## Detoxification and Withdrawal

Opioid detoxification traditionally has been achieved via short-term substitution therapy followed by abstinence. Opioid withdrawal can begin within 8–12 hours of last use and generally peaks at 24–72 hours, with acute withdrawal symptoms resolving within 5–7 days; however, the time course is dependent on the half-life of the agent being used. A protracted abstinence syndrome may continue for an additional 6–8 months and includes dysphoria, fatigue, insomnia, and irritability ([Martin and Jasinski 1969](#)). Full (methadone) and partial (buprenorphine) opioid agonist medications have been used for detoxification. Over the course of 1–4 weeks, opioid-dependent individuals are tapered off medication and encouraged to remain abstinent with continued psychosocial treatment.

A recent study compared taper regimens of 1, 2, and 4 weeks in 70 prescription opioid-dependent adults attending an outpatient clinic ([Sigmon et al. 2013](#)). On all outcome measures, the 4-week taper condition fared better, showing greater abstinence rates at week 5 compared with the 2-week and 1-week taper groups (63% vs. 29% vs. 29%) and also at week 12 (50% vs. 16% vs. 20%); the 4-week group also had more responders, better retention, and greater posttaper naltrexone ingestion. In a multisite trial, [Woody et al. \(2008\)](#) examined longer taper durations in 152 opioid-dependent youths (ages 15–21 years) randomly assigned to 12 weeks of buprenorphine–naloxone treatment or a 14-day detoxification protocol. Compared with youths receiving the 14-day detoxification regimen, those receiving the 12-week treatment had significantly fewer positive opioid urine test results and higher retention over the 12-week study. However, participants did not differ on any outcome measures at 6, 9, and 12 months posttreatment.

Across studies, longer taper durations are associated with higher abstinence rates during treatment ([Dunn et al. 2011](#)). Furthermore, a systematic Cochrane review found that across studies, heroin-dependent adults who received methadone only for detoxification showed greater illicit heroin use and worse retention compared with those who received methadone for both detoxification and maintenance ([Mattick et al. 2009](#)).

Attempts to augment detoxification with clonidine, an  $\alpha$ -adrenergic agonist, have been investigated. Some studies have been unsuccessful or have shown no advantage for clonidine over agonist detoxification ([Gold et al. 1978, 1980](#); [Ling et al. 2005](#)), and a systematic review found side effects to be a significant issue ([Gowing et al. 2003](#)). A multisite clinical trial across inpatient ( $N=113$ ) and

outpatient ( $N=231$ ) treatment settings compared buprenorphine-naloxone with clonidine in a 13-day opioid detoxification regimen. Buprenorphine-naloxone was more effective in achieving treatment success (retention and negative screen on last day) than clonidine among both inpatients (77% vs. 22%) and outpatients (29% vs. 5%; [Ling et al. 2005](#)). When used in conjunction with buprenorphine, however, clonidine was associated with a longer duration of opioid abstinence in one 14-week placebo-controlled trial ([Kowalczyk et al. 2015](#)).

Rapid detoxification procedures also have been developed, including 1) rapid withdrawal induction with naltrexone (followed by high doses of clonidine and benzodiazepines to attenuate associated symptoms) and 2) rapid withdrawal under general anesthesia (with administration of numerous and varied medications to manage symptoms). These methods generally are not recommended; the latter in particular has been associated with multiple deaths within 72 hours of the procedure ([Whittington et al. 2000](#)). Although detoxification is important, rapidity should not be emphasized. Given the chronic, relapsing nature of opioid use disorders, first-line treatment has shifted toward lengthier taper durations and maintenance therapy followed by relapse prevention.

## Maintenance Therapy

### **Methadone**

Methadone maintenance treatment (MMT) is the most common form of maintenance therapy and involves closely monitored daily administration by licensed physicians at federally regulated treatment centers. Patients must attend

clinic daily unless they earn take-home privileges for meeting clinic criteria such as employment and long-term abstinence (2 years or more). Patients must be at least 18 years old and must have had an opioid use disorder for at least 1 year. Since its introduction in 1964, MMT has been the focus of numerous clinical trials that collectively indicate that MMT clearly reduces illicit opioid use and improves treatment retention ([Fullerton et al. 2014](#); [Mattick et al. 2009](#)). MMT also has been associated with decreased mortality ([Gunne and Grönbladh 1981](#); [Kinlock et al. 2007](#)), reduced nonopioid drug use ([Faggiano et al. 2003](#)), and decreased drug-related HIV risk behaviors ([Sees et al. 2000](#)). Psychosocial counseling focusing on lifestyle changes significantly improves outcomes ([McLellan et al. 1993](#)), and studies have found that interventions such as contingency contracting and voucher incentives are also efficacious ([Brooner et al. 2007](#)).

Because of the recently discovered association between MMT and QTc interval prolongation, which can be fatal, the FDA issued a black box warning in 2006. The Substance Abuse and Mental Health Services Administration (SAMHSA) also issued recommendations for physicians who provide MMT, which included notifying patients of potential cardiac complications, screening patients for cardiac conditions, and, when indicated, conducting a pretreatment and 1-month electrocardiogram ([Center for Substance Abuse Treatment 2005](#)).

## **Buprenorphine**

Buprenorphine was approved by the FDA for the office-based treatment of opioid use disorder in 2002. In order to prescribe buprenorphine, physicians must undergo an 8-hour training and be granted approval from the U.S.

Department of Health and Human Services, after which they may see 30 patients in the first year and 100 per year thereafter.

Early trials of buprenorphine established its efficacy in treating opioid use disorders. A 25-week RCT compared buprenorphine with methadone and found the two medications to be equally effective in reducing opioid use and maintaining participants in treatment (R.E. [Johnson et al. 1992](#)). A systematic Cochrane review evaluated evidence comparing buprenorphine maintenance with placebo and methadone maintenance ([Mattick et al. 2014](#)). Fixed-dose results suggested that compared with placebo, buprenorphine improved treatment retention at any dose but suppressed illicit opioid use only at doses of 16 mg or higher. Compared with methadone, buprenorphine did not differ in treatment retention or suppression of opiate use at medium or high doses (methadone: medium = 40–85 mg, high  $\geq$  85 mg; buprenorphine: medium=7–15 mg, high $\geq$ 16 mg), although low-dose methadone ( $\leq$ 40 mg) was associated with better retention than low-dose buprenorphine (2–6 mg). Studies that used flexible dosing found that compared with methadone maintenance, buprenorphine retained fewer participants, but among those retained in treatment, no difference was seen in suppression of opioid use. In summary, whereas methadone at low or flexible doses appears to be more effective than buprenorphine in retaining patients in treatment, methadone at medium to high fixed doses is no different from buprenorphine in treatment retention or opioid use suppression.

## **Buprenorphine-Naloxone**

Buprenorphine-naloxone was introduced to address the risks of diversion and injection overdose associated with buprenorphine alone. Naloxone is a high-affinity  $\mu$  opioid receptor antagonist. It has high bioavailability when injected and therefore prevents abuse and overdose by immediately counteracting the agonist properties of buprenorphine, resulting in acute withdrawal. However, sublingually, naloxone has low bioavailability; therefore, when the combination is administered sublingually, as is customary, the individual experiences the intended agonist effect of buprenorphine without experiencing withdrawal. A buprenorphine-to-naloxone ratio of 4:1 has been established.

[Fudala et al. \(2003\)](#) conducted the seminal efficacy study of office-based treatment of opioid use disorders using combination buprenorphine-naloxone compared with buprenorphine alone or placebo. The 4-week double-blind, randomized trial ( $N=326$ ) found buprenorphine alone and buprenorphine-naloxone to have greater efficacy than placebo, as measured by percentage of negative opioid drug screens (20.7% vs. 17.8 vs. 5.8) and reductions in opioid craving. The open-label phase ( $N=461$ ) demonstrated that both the buprenorphine-naloxone combination and buprenorphine alone can be safely administered in an outpatient office-based setting. The study authors concluded that buprenorphine-naloxone is at least as good as buprenorphine alone and better than placebo.

[Weiss et al. \(2011\)](#) conducted a multisite, randomized, two-phase adaptive treatment design examining brief and extended buprenorphine-naloxone treatment for prescription opioid dependence ( $N=653$ ). Brief treatment included a 2-week stabilization phase, followed by a 2-week

taper and an 8-week postmedication follow-up assessment (12-week treatment), whereas the extended treatment condition included 12 weeks of buprenorphine-naloxone treatment, followed by a 4-week taper and an 8-week postmedication follow-up (24-week treatment). Extended treatment produced more successful outcomes compared with brief treatment, but only while subjects were maintained on buprenorphine-naloxone; at 8-week postmedication follow-up, there were significant reductions in treatment success rates.

## **Buprenorphine Implants**

Further efforts to reduce diversion, improve adherence, and enhance outcomes include the development of subcutaneous buprenorphine implants, which were approved by the FDA in 2016. A randomized, placebo-controlled 6-month multisite trial ([Ling et al. 2010](#)) found buprenorphine implants to be efficacious as evidenced by greater mean percentage of negative opioid drug screens from weeks 1 to 16 compared with placebo (40.4% vs. 28.3%) and for the entire 24-week period (36.6% vs. 22.4%). The implant group also had higher retention rates (65.7% vs. 30.9%) and fewer clinician- and patient-rated withdrawal symptoms. A subsequent study confirmed the safety and efficacy of buprenorphine implants in reducing opioid use, improving retention, reducing craving and withdrawal ratings, and increasing global ratings of improvement compared with placebo ([Rosenthal et al. 2013](#)). Importantly, the authors reported that buprenorphine implants were noninferior to the commonly used sublingual buprenorphine formulation on percentage of negative urine drug screens during the 24-week study.

## Maintenance Treatment During Pregnancy

Opioid-dependent pregnant women warrant special consideration. MMT during pregnancy has been considered the gold standard of care and is associated with reduced fetal and maternal morbidity, greater prenatal treatment attendance, and improved fetal outcomes overall ([Jones et al. 2008](#); [Kaltenbach et al. 1998](#)). However, these studies were conducted in patients dependent on illicit opioids, and there have been no systematic investigations of the management of opioid use disorders in pregnant women taking prescription opioids.

Neonatal abstinence syndrome involves dysfunction of respiratory, gastrointestinal, and autonomic nervous systems; is common among prenatally exposed neonates, with incidence rates ranging from 45% to 97% ([Cleary et al. 2010](#)); and often requires inpatient detoxification. Although longitudinal studies have suggested that MMT during pregnancy does not impair offspring cognitive performance at age 4 years, performance across groups was significantly lower than in normative samples ([Kaltenbach and Finnegan 1984](#)). Buprenorphine monotherapy is a viable and perhaps desirable alternative that produces less fetal heart rate suppression and less severe neonatal abstinence syndrome compared with methadone ([Jones et al. 2012](#)). Studies of maintenance treatment and detoxification in pregnant women with prescription opioid use disorders are clearly needed.

## Relapse Prevention

### Oral Naltrexone

Naltrexone has been approved by the FDA for the treatment of opioid use disorders since 1984. It acts by blocking the  $\mu$  opioid receptor for 24–72 hours (depending on dose), preventing the individual from experiencing drug-induced euphoria. Continued abstinence through relapse prevention allows recovery of the endogenous opioid system and relief of protracted abstinence symptoms. Naltrexone was introduced in addiction treatment in the 1970s as an orally administered nonaddictive medication with hopes of wide acceptance and effectiveness. However, numerous clinical trials have reported poor outcomes compared with placebo, no treatment, or other pharmacological treatment ([Minozzi et al. 2011](#); [Schottenfeld et al. 2008](#)). Moreover, adherence rates are generally low, and overdose due to relapse in previously tolerant opioid-dependent individuals poses a serious risk for oral naltrexone use. To address poor adherence and associated overdose risk of relapse, XR-NTX was developed and approved by the FDA in 2010.

### **Extended-Release Injectable Naltrexone**

The seminal study of XR-NTX was conducted at 13 clinical sites in Russia ([Krupitsky et al. 2011](#)), where opioid agonist treatment is illegal. In this 24-week double-blind, placebo-controlled, randomized trial ( $N=250$ ), participants receiving XR-NTX had a significantly greater median proportion of confirmed weeks abstinent compared with placebo (90% vs. 35%), higher median numbers of opioid-free days (99.2% vs. 60.4%), longer treatment retention (>168 days vs. 96 days), and greater reductions in craving scores. Among those who entered the open-label phase of the study ( $n=114$ ), 62.3% completed the phase and 50.9%

were abstinent at the end of the trial ([Krupitsky et al. 2013](#)).

XR-NTX has been examined in high-risk populations, including incarcerated individuals and health care professionals. In an open-label pilot study of XR-NTX in 27 prerelease prisoners with a history of opioid use disorders during the year before incarceration ([Gordon et al. 2015](#)), participants received one prerelease injection of XR-NTX followed by six injections after release to the community. Compared with participants who completed fewer than six community injections, those who completed all six were less likely to test positive for opioids at any point during the study (0% vs. 62.5%). Health care professionals with opioid use disorders also showed favorable responses to XR-NTX in a prospective noncomparison study ([Gastfriend et al. 2014](#)). After a 2-week detoxification period, all participants ( $N=38$ ) were offered XR-NTX for up to 24 months; 39.5% remained on XR-NTX at 24 months, and 90% remained abstinent while maintained on the medication.

According to a SAMHSA advisory, subgroups most likely to benefit from XR-NTX include patients unsuccessful with methadone or buprenorphine, those who prefer a less stigmatizing and more convenient alternative, those opposed to agonist therapy, highly motivated individuals, and adolescents or young adults for whom access to treatment facilities is often restricted by governmental regulations ([Substance Abuse and Mental Health Services Administration 2012](#)).

## Overdose Prevention

Recently, overdose education and naloxone rescue kits have been developed and used in various settings to address the growing opioid overdose epidemic. Naloxone is an opioid antagonist that is capable of reversing opioid overdose by decoupling opioids from the opioid receptor and inducing acute withdrawal. It can be administered via injection or nasal spray. Access has increased in the past 5 years, with 44 states plus the District of Columbia passing immunity laws that enable physicians to prescribe the drug or civilians and first responders to administer the drug without fear of civil, criminal, or professional liability ([National Conference of State Legislatures 2017](#)). Thirty-four states plus the District of Columbia also have passed various types of Good Samaritan laws that encourage individuals witnessing or experiencing an overdose to call 911 or seek emergency medical assistance by protecting help-seeking individuals from prosecution for minor drug-related crimes.

---

## **Tobacco-Related Disorders**

---

According to the 2014 National Survey on Drug Use and Health, 66.9 million people, or 25% of the population ages 12 years and older, were current users of a tobacco product, with 21% being current cigarette smokers ([Center for Behavioral Health Statistics and Quality 2015](#)). Approximately 4.5% were current cigar smokers, 1% were current pipe tobacco smokers, and 3% used smokeless tobacco. Few tobacco users are successful in permanently quitting in their initial attempt. Most tobacco users consume tobacco for many years and cycle through periods

of abstinence and relapse. Failure to grasp the chronic nature of tobacco use disorders can lead to discouragement in health care providers and impede the treatment of tobacco use over time. According to data from the 2001–2010 National Health Interview Surveys, in 2010 more than 70% of U.S. smokers reported that they wanted to quit, and 52% reported having tried to quit in the past year ([Centers for Disease Control and Prevention 2011](#)). Unfortunately, most of these quit attempts are unaided, and most smokers return to regular smoking within a few weeks ([Ward et al. 1997](#)).

## Counseling Strategies

Behavioral strategies, including in-person counseling, telephone quitlines, and self-help materials, provide a small but important effect in achieving smoking cessation. Telephone counseling is readily available in the United States through the publicly funded quitline 1-800-QUIT-NOW (1-800-784-8669). A pooled estimate of 47 trials indicated that increasing the amount of behavioral support increased the chance of successful smoking cessation by 10%–25% ([Stead et al. 2015](#)).

## Pharmacotherapy

Current practice guidelines recommend the use of an effective medication at every quit attempt unless medically contraindicated or within special populations, such as pregnant women and adolescents, for which there is limited evidence of effectiveness ([Fiore et al. 2008](#)). Seven first-line medications are safe, effective, and FDA approved for

smoking cessation; these include nicotine replacement therapies (NRTs; patch, gum, lozenge, nasal spray, inhaler), bupropion sustained release (SR), and varenicline. Generally, cessation medications double the quit rate relative to placebo (20% vs. 10%; [Cahill et al. 2013](#)).

## **Nicotine Replacement Therapies**

NRTs partially replace the nicotine obtained from cigarettes and are intended to aid in quitting by reducing the severity of nicotine withdrawal. A recent Cochrane review ([Stead et al. 2012](#)) of 150 studies found that NRT increased cessation rates to 17%, compared with 10% with placebo (number needed to treat [NNT]=15). Nicotine patches, gum, and lozenges are available over the counter. The nicotine inhaler and nasal spray are prescription medications. Nicotine from the gum and lozenge is absorbed through the buccal mucosa. Nicotine from the inhaler and nasal spray is absorbed through the oropharynx and nasal mucosa, respectively. The nicotine patch, which is designed for skin absorption, has the advantage of once-a-day application and as result has higher adherence rates.

The nicotine gum is available in 2- and 4-mg doses, with the 4-mg nicotine gum recommended for individuals who smoke 25 or more cigarettes a day. Smokers should be instructed to use one piece of gum every 1-2 hours (maximum of 24 pieces per day) for the first weeks and to taper the frequency over the next 6 weeks. The gum should be slowly chewed until a “peppery” taste emerges, and then “parked” between the cheek and the gum to facilitate absorption. The gum should be intermittently slowly chewed and parked until the taste dissipates, typically in about 30 minutes. Common side effects include hiccups, dyspepsia, and jaw discomfort.

The lozenge is available in 2- and 4-mg doses, with the 4-mg dose recommended for individuals who smoke their first cigarette within 30 minutes of awakening. In general, at least 9 lozenges per day should be used for the first 6 weeks, with a maximum of 20 lozenges per day. Common adverse effects include hiccups, nausea, and heartburn.

The patch has the advantage of daily dosing, thus enhancing compliance. For patients who smoke more than 10 cigarettes a day, a standard course would include 21 mg for 6 weeks followed by 14 mg for 2 weeks and then 7 mg for 2 weeks. About 50% of patients will experience a mild local skin reaction ([Fiore et al. 2008](#)), which requires discontinuation in about 5% of patients. Rotating the site on a daily basis can help prevent skin reactions. Insomnia and vivid dreams also may occur; removing the patch before bedtime can reduce the disruption in sleep.

The nicotine inhaler delivers 4 mg of nicotine over 80 inhalations. Recommended dosing is 6-16 cartridges a day for 3 months, followed by tapering over the subsequent 3 months. Coughing and rhinitis are common side effects. Exacerbation of reactive airway disease can occur.

The nicotine nasal spray produces the highest nicotine level compared with other forms of NRT. The initial dose is 0.5 mg to each nostril (total 1 mg) per hour as needed, with a minimum of 8 doses and a maximum of 40 doses per day. The recommended duration of therapy is 3-6 months. Most patients experience varying degrees of nasal irritation. Other common side effects include transient changes in taste and smell. Severe reactive airway disease is a contraindication.

Of note, the use of NRT is not an independent risk factor for an acute myocardial infarction. However, NRT should be used with caution in patients who have unstable angina

pectoris or severe arrhythmias and who have experienced a myocardial infarction within the past 2 weeks. Some smokers may benefit from a longer course of NRT treatment. [Schnoll et al. \(2015\)](#) compared 8 weeks (standard), 24 weeks (extended), and 52 weeks (maintenance) of nicotine patch treatment in combination with 12 weeks of smoking cessation counseling. At 6 months, 22% of the participants in the standard treatment group were abstinent, compared with 27% in the extended and maintenance groups.

## **Bupropion SR**

In the late 1990s, the SR formulation of bupropion was approved by the FDA for smoking cessation and marketed under the trade name Zyban. Bupropion SR is an antidepressant with noradrenergic and dopaminergic effects and antagonist action at the nicotinic acetylcholine receptor. In a recent systematic review ([Hughes et al. 2014](#)), bupropion was associated with a significantly higher rate of smoking abstinence at 6 months compared with placebo (19.7% vs. 11.5%). Bupropion may work by blocking nicotine effects, relieving withdrawal, or decreasing depressed mood. A standard bupropion SR course begins with one 150-mg tablet taken by mouth once a day for 3 days, at which point the dosage is increased to one tablet taken by mouth twice a day (separated by at least 8 hours) for 7–12 weeks. The tobacco quit date is 1 week after starting medication. If the treatment is successful, some patients benefit from continued treatment for up to 6 months to prevent relapse.

Bupropion SR is generally well tolerated. Bupropion reduces seizure threshold, and seizures are estimated to occur in 1 out of 1,000 treated patients ([Hughes et al.](#)

2014). Contraindications include seizure disorders, eating disorders, and monoamine oxidase inhibitor use within 14 days.

## Varenicline

Varenicline is a partial agonist at the  $\alpha_4\beta_2$  nicotinic receptor that relieves symptoms of nicotine withdrawal and blocks nicotine from attaching to the receptor, thus reducing the rewarding properties of smoking (Coe et al. 2005). Numerous controlled studies support the efficacy of varenicline for smoking cessation. Two early studies that included more than 2,000 participants (Gonzales et al. 2006; Jorenby et al. 2006) were 12-week RCTs comparing varenicline, bupropion, and placebo. Rates of continuous abstinence for the last month of the treatment phase were 44% for varenicline, 30% for bupropion, and 18% for placebo. Continuous abstinence rates for 1 year for varenicline, bupropion, and placebo were 23%, 14.6%, and 10.3%, respectively, in one study (Jorenby et al. 2006). A standard course is typically 0.5 mg every day for 3 days, then 0.5 mg twice a day for 4 days, and then 1 mg twice a day with food. The target quit date is 1 week after starting varenicline. If clinically warranted, the initial total 12-week course can be continued for an additional 12 weeks if initial treatment is successful.

## Black Box Warnings

In 2009, a black box warning was added to the packaging information for both varenicline and bupropion after an FDA review of postmarketing data concluded that these medications could potentially increase the risk of depression, suicidality, agitation, worsening of preexisting

psychiatric illnesses, and changes in behavior in treated individuals ([U.S. Food and Drug Administration 2009](#)). These warnings call for close monitoring for symptoms or changes in behavior. A 2015 meta-analysis of 39 RCTs with almost 11,000 participants found no evidence of an increased risk of suicide, suicide attempts, suicidal thoughts, depression, aggression, or death in participants taking varenicline compared with placebo ([Thomas et al. 2015](#)), confirming results of an earlier meta-analysis by [Gibbons and Mann \(2013\)](#) that included 17 RCTs conducted by Pfizer and a large data set from the U.S. Department of Defense.

## Combination Therapies

Previous research has indicated that combination NRT—patch and lozenge—increased quit rates compared with either placebo or monotherapy ([Piper et al. 2009](#)).

Varenicline combined with bupropion has been investigated in several RCTs. Of the prospective trials, one showed a greater 4-week smoking abstinence for weeks 8–11 with combination therapy (39.8%) than with monotherapy (25.9%) (odds ratio [OR]=1.89; 95% confidence interval [CI]=1.07–3.35). [Ebbert et al. \(2014\)](#) found greater prolonged abstinence (53% vs. 43% at 12 weeks and 37% vs. 28% at 26 weeks) in the combination group compared with varenicline plus placebo, although results were not significant at 52 weeks. In a study by [Rose and Behm \(2014\)](#), smokers who used the nicotine patch and did not reduce smoking were randomly assigned to 12 weeks of varenicline and bupropion SR or varenicline plus placebo. Participants receiving the combination had significantly higher abstinence rates compared with the varenicline plus placebo group (40% vs. 26%). The

combination treatment was significantly more effective in males and highly dependent smokers ([Rose and Behm 2014](#)).

## **Second-Line Medications**

Second-line medications should be considered on a case-by-case basis if first-line medications (alone or in combination) are ineffective or contraindicated. Several medications are effective but have a more limited role because of potential side effects and lack of FDA approval for smoking cessation. Medications in this category include clonidine and nortriptyline ([Fiore et al. 2008](#)).

## **Special Populations**

### **Women Who Are Pregnant or Who Are Trying to Conceive**

The harmful effects of smoking during pregnancy are well known and include small-for-gestational-age neonates, stillbirth, preterm birth, and placenta previa ([Jauniaux and Burton 2007](#)). Current guidelines recommend the use of in-person psychosocial strategies that exceed minimal advice to quit smoking. Although quitting smoking during the first trimester will produce the greatest benefit, quitting at any time can be beneficial. In a recent meta-analysis that excluded potentially biased, non-placebo-controlled RCTs, NRT was no more effective than placebo ([Coleman et al. 2015](#)). Evidence is insufficient to recommend the use of bupropion or varenicline during pregnancy.

### **Children and Adolescents**

Tobacco use is typically initiated and established during adolescence ([U.S. Department of Health and Human Services 2012](#)). In the 2014 National Youth Tobacco Survey, about 25% of high school students reported current use of a tobacco product, and 13% reported use of two or more tobacco products ([Rudd et al. 2016](#)). E-cigarettes (13%) were the most commonly used tobacco product. Current treatment guidelines recommend that clinicians assess for tobacco use and strongly recommend abstinence in children and adolescents. Psychosocial interventions, especially those that contain cognitive-behavioral components, have been found to be efficacious in the short term for the treatment of adolescent smokers ([Simon et al. 2015](#)). Contingency management and motivational interviewing have shown some effectiveness as stand-alone treatments, and strategies that include elements of the transtheoretical model of change also have shown promise.

## **Individuals With Comorbid Psychiatric Disorders**

Despite the significant decline in smoking rates in the general population, comparable declines in smoking rates among smokers with psychiatric disorders have not been realized. According to combined data from the 2009-2011 National Survey on Drug Use and Health, approximately 20% of adults had some form of a mental illness in the past year, of whom 36% were current smokers, compared with 21% of adults with no mental illness ([Centers for Disease Control and Prevention 2013](#)). In a recent study examining prevalence of cigarette smoking among adults with and without psychiatric disorders, 64% of participants with schizophrenia and 44% of those with bipolar disorder

reported that they smoked regularly, compared with 19% of control participants without psychiatric illness ([Dickerson et al. 2013](#)). Unfortunately, individuals with mental illnesses are frequently excluded from clinical studies focused on the treatment of nicotine dependence, and smoking cessation therapies are not routinely offered to patients with severe mental illness. Mental health professionals commonly have permissive attitudes toward smoking and mistakenly assume that patients with comorbid psychiatric and substance use disorders are not interested in quitting ([Sheals et al. 2016](#)). These attitudes and misconceptions undermine the provision of smoking cessation interventions in these populations.

Evidence shows that smoking cessation therapies are both effective and well tolerated in populations with severe mental illness. In a recently completed meta-analysis, [Roberts et al. \(2016\)](#) examined RCTs in which NRT, bupropion, or varenicline (as monotherapy or in combination) was compared with placebo or another FDA-approved medication in motivated smokers with severe mental illness (including bipolar disorder, depressive psychoses, delusional disorder, schizophrenia, and schizoaffective disorder). Bupropion and varenicline were both found to be more efficacious than placebo (ORs=4.51 and 5.17, respectively). A significant difference was not detected between bupropion plus NRT and placebo plus NRT. Both bupropion and varenicline were well tolerated, with no significant differences in dropouts resulting from adverse events, including change in mental status and suicidal ideation. Clinical practice guidelines recommend a treatment duration of 12 weeks, but more recent evidence indicates that maintenance pharmacotherapy for 1 year

may improve sustained abstinence rates in individuals with schizophrenia spectrum disorders ([Evins and Cather 2015](#)).

Both NRT and bupropion have been found to be efficacious in patients with current or past depression ([Gierisch et al. 2012](#)). Varenicline has been found to be effective in patients with stably treated depression or past depression without causing an exacerbation in symptoms ([Anthenelli et al. 2013](#)).

Admission to a smoke-free psychiatric hospital is a natural opportunity to provide smoking cessation treatment. Daily smokers with and without an intention to quit were recruited from several locked psychiatric units and randomly assigned to interventions that included tailored counseling with an emphasis on readiness to quit and NRT availability after discharge ([Schuck et al. 2016](#)). An impressive 76% of eligible smokers enrolled, of whom 88% requested study-provided NRT. Those with more severe psychiatric symptoms were more likely to request NRT posthospitalization ( $P<0.01$ ). Participants who requested NRT at discharge were more likely to make a 24-hour quit attempt and to self-report abstinence at the 1-week follow-up (54% quit attempt, 14% abstinent) compared with participants who did not request NRT at discharge (25% quit attempt, 4% abstinent) ( $P<0.05$ ).

## **Individuals With Comorbid Substance Use Disorders**

Individuals who are receiving treatment for a substance use disorder have smoking rates two to four times higher than those in the general population ([Guydish et al. 2016](#)) and are more likely to die from smoking-related illnesses than from complications from drug use ([Baca and Yahne 2009](#)).

However, many individuals receiving substance use disorder treatment continue to smoke despite achieving abstinence from alcohol and drugs ([McClure et al. 2015](#)). Current treatment guidelines recommend that patients with substance use disorders should be offered smoking cessation treatment ([Fiore et al. 2008](#)). It has been suggested that varenicline may be the most effective treatment for alcohol use disorders and comorbid alcohol and tobacco use disorders because alcohol produces activation in the mesolimbic pathway through its effects on nicotinic acetylcholine receptors ([Söderpalm et al. 2000](#)). Varenicline has been reported to decrease alcohol craving and consumption in smoking cessation trials ([Fucito et al. 2011](#); [Mitchell et al. 2012](#)).

In a recent review of smoking cessation interventions during substance use disorder treatment, a variety of pharmacotherapy and behavioral treatment options significantly improved smoking outcomes ([Thurgood et al. 2015](#)). Opioid-dependent smokers may present a particular challenge. Smoking prevalence rates among opioid-dependent individuals are fourfold higher than in the general population, and current pharmacotherapy outcomes have been disappointing and typically worse than those seen in the general population of smokers ([Miller and Sigmon 2015](#)). Clearly, additional research to understand the relation between tobacco and substance use disorders is warranted, given that smoking cessation has the potential to improve the morbidity and mortality associated with these common disorders.

---

## Stimulant-Related Disorders

---

The search for a pharmacotherapeutic treatment for cocaine and amphetamine use disorders has been extremely active over the last 20 years, with controlled trials of antidepressants, anticonvulsants, dopamine agonists and antagonists, and many other agents. Unfortunately, many medications that show promise in animal models of stimulant dependence and/or positive outcomes in small uncontrolled trials fail to decrease drug use by objective measures in larger controlled trials. In addition, many clinical trials in stimulant-dependent individuals are flawed by high dropout rates and medication noncompliance. To date, no medications have clearly shown efficacy in the treatment of cocaine or amphetamine dependence; however, the medications discussed in this section have shown promise, often in subgroups of individuals studied.

## Agonist Replacement Strategies

The focus of numerous studies has been agonist replacement in which a pharmacologically similar agent is substituted for the stimulant of abuse. As discussed in other sections of this chapter, agonist replacement therapies are effective in both nicotine and opioid dependence. An ideal agonist replacement therapy for stimulant dependence should share some pharmacological and behavioral effects with cocaine or amphetamine but have less abuse potential. Unfortunately, many of the agents that have shown promise do not meet these criteria.

Methylphenidate, a piperidine derivative that produces effects similar to those of cocaine at the dopamine transporter and is approved for the treatment of attention-

deficit/hyperactivity disorder (ADHD), has been tested in cocaine- and amphetamine-dependent individuals with and without ADHD. Although the results of methylphenidate treatment in individuals with cocaine and amphetamine dependence generally have been negative ([Stoops and Rush 2013](#)), findings have been mixed in individuals with ADHD, with positive results seen in cocaine- and amphetamine-dependent individuals taking 60 mg/day ([Konstenius et al. 2010](#); [Levin et al. 2007](#)) and negative results seen in cocaine-dependent individuals taking 80–90 mg/day ([Levin et al. 2006](#); [Schubiner et al. 2002](#)).

Several trials have indicated that D-amphetamine and methamphetamine can decrease cocaine use in cocaine-dependent individuals ([Grabowski et al. 2001, 2004](#); [Mooney et al. 2009](#); [Shearer et al. 2003](#)). However, trials of D-amphetamine in amphetamine dependence have been negative ([Galloway et al. 2011](#); [Longo et al. 2010](#)).

These studies suggest that stimulant replacement warrants further investigation, but it must be noted that the abuse and diversion potential of methylphenidate and amphetamines limits the potential widespread utility of this approach ([Stoops et al. 2004](#)).

## Other Pharmacotherapeutic Agents

### **Bupropion**

Bupropion, an antidepressant with dopaminergic activity, has been tested in multiple clinical trials in both cocaine and methamphetamine dependence. The results were largely mixed, but bupropion appears to have some efficacy when combined with consistent behavioral treatment in

cocaine dependence ([Poling et al. 2006](#)) and in methamphetamine-dependent users who had lighter use ([Elkashef et al. 2008](#); [Shoptaw et al. 2008](#)).

## **Disulfiram**

In addition to its effects on alcohol metabolism, disulfiram blocks the enzymatic degradation of both cocaine and dopamine. Investigators have hypothesized that increased dopamine levels may help improve hedonic tone (i.e., sense of well-being, pleasure, or contentment) in cocaine-dependent individuals, and the increased cocaine levels have been shown to increase cocaine-related anxiety and dysphoria in individuals pretreated with disulfiram ([Hameedi et al. 1995](#)). Regardless of the mechanism, four clinical trials to date have reported that disulfiram reduces cocaine use in cocaine-dependent patients ([Carroll et al. 2004](#); [George et al. 2000](#)). Given these results, disulfiram definitely should be considered in the treatment of cocaine dependence as long as the individual is willing to remain alcohol-free and understands the potential for increased toxicity with cocaine use.

## **Modafinil**

Modafinil, a novel stimulant and glutamatergic agent that is FDA approved for narcolepsy, has been tested in both cocaine and amphetamine dependence. Although initial trials were positive ([Dackis et al. 2005](#)), subsequent trials found that efficacy was limited to individuals who did not have a history of alcohol dependence and to men ([Anderson et al. 2009](#); [Dackis et al. 2012](#)). Trials of modafinil are ongoing, but the medication is well tolerated and may be useful in reducing cocaine withdrawal symptoms and

helping some individuals attain abstinence ([Malcolm et al. 2002](#)).

## Topiramate

There have also been several promising studies with topiramate, an anticonvulsant agent that has shown promise in alcohol dependence (see “Topiramate” subsection earlier in this chapter). In one placebo-controlled trial of cocaine dependence, topiramate-treated subjects were more likely than placebo-treated subjects to achieve 3 weeks of continuous abstinence and to be rated as clinically improved ([Kampman et al. 2004](#)).

## GABAergic and Glutamatergic Modulators

Several other promising agents that modulate GABAergic and glutamatergic systems are under investigation for the treatment of stimulant use disorders. Both vigabatrin and *N*-acetylcysteine had strong effects in animal models of cocaine dependence but showed less promise in clinical trials.

Vigabatrin ( $\gamma$ -vinyl-GABA), an anticonvulsant that increases GABA neurotransmission by inhibiting GABA transaminase, showed promise in several open-label trials of both cocaine and methamphetamine dependence. One placebo-controlled trial reported higher rates of abstinence (as assessed by both self-report and urine drug screening) in the vigabatrin-treated group with cocaine dependence ([Brodie et al. 2009](#)), whereas a multisite trial ([Somoza et al. 2013](#)) found no difference in any outcomes in cocaine-

dependent individuals taking vigabatrin compared with placebo. However, compliance with vigabatrin was low in this trial, calling the negative results into question.

*N*-acetylcysteine is a glutamatergic agent that also has shown consistent effects in animal models of cocaine dependence ([Baker et al. 2003](#)). Although an initial pilot study with a crossover design showed promise in cocaine dependence ([LaRowe et al. 2006](#)), a follow-up double-blind, placebo-controlled trial ([LaRowe et al. 2013](#)) found no difference between two doses of *N*-acetylcysteine and placebo in any outcome measures. However, a reduction in cocaine-positive urine drug screens was seen in a small subset of individuals who were abstinent at initiation of study drug, suggesting that *N*-acetylcysteine may be more efficacious in relapse prevention than in initiating abstinence. Further studies are required to assess this possibility.

---

## Conclusion

---

Effective pharmacological treatments are available for alcohol, opioid, and tobacco use disorders, but studies suggest that these treatments are underused. The search for a medication treatment for stimulant use disorders remains an active area of research, with a wide range of agents being tested across hundreds of clinical trials. Given the devastating personal and societal effects of substance-related disorders, pharmacotherapy should be considered when appropriate as part of a comprehensive treatment plan.

# CHAPTER 51

## Treatment of Personality Disorders

Marissa Miyazaki, M.D.

Daphne Simeon, M.D.

Eric Hollander, M.D.

**Personality disorders** are among the most challenging conditions faced by clinicians. The two main approaches to the treatment of personality disorders are psychosocial treatment and medications. Psychotherapy continues to be the treatment foundation for all personality disorders, and psychotherapy studies on the whole have shown improvement with treatment—two to four times greater than the improvement seen in the control conditions ([Perry and Bond 2000](#)).

The main indications for using medications in treating personality disorders are periods of decompensation, crises, and hospitalizations; the longer-term management of symptom clusters that are maladaptive and may be responsive to medication; and the reappearance or worsening of comorbid conditions. The underlying rationale for medication use is that associated behavioral traits might have neurobiological and psychological correlates ([Oquendo et al. 2005](#); [Simeon et al. 1992](#)).

In this chapter we summarize the literature to date on the pharmacological treatment of personality disorders. We begin with a brief overview of current conceptualizations of personality and what constitutes a “personality disorder,” followed by a discussion of the treatment of Cluster B disorders (which has the largest evidence base), Cluster A disorders, and Cluster C disorders. Findings from neuroimaging, neuroendocrine and cognitive-behavioral studies pertinent to the understanding of personality disorders are summarized. The chapter concludes with a brief overview of emerging areas of research and their implications for our understanding of the pathophysiology and treatment of personality disorders.

---

### Models of Personality

---

Whereas nobody doubts the existence of personality, what constitutes its disordered form has been controversial. There is little disagreement on the limitations of the current categorical classification of personality disorders, but consensus on a unified model has been lacking. Much of the debate has centered on dimensional versus categorical models of personality disorders. The alternative dimensional model for personality disorders in Section III of the *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition

(DSM-5; [American Psychiatric Association 2013](#)), has two main criteria: impairment in personality functioning and one or more pathological personality traits.

The founder of personality psychology, [Allport \(1937\)](#), in one of the earliest conceptualizations of personality disorders, theorized that “personality ‘is’ something and personality ‘does’ something” (p. 48). In the nearly 80 years since then, research into what personality “is” (i.e., trait structural models) has dominated the field ([Ro et al. 2013](#)). Recently there has been increased attention on what personality “does”—that is, the functional aspects of personality and how it serves to adapt individuals’ behaviors to their situations ([Ro and Clark 2009](#)). Distinguishing personality functioning from traits is important conceptually, because simply having extreme traits is not necessarily pathological. From an evolutionary perspective, [Livesley and Jang \(2000\)](#) theorized that severe personality pathology reflects a failure of three adaptive systems: a “self-system” (i.e., development of a stable concept of self and, correspondingly, of others) and two “other-systems” (i.e., the capacity for close personal relations and intimacy, and the ability to function effectively at a societal level). The consequence of this system failure is an inability to handle major life tasks—in effect, Freud’s *lieben und arbeiten* (to love and to work).

The heterogeneity and absence of evidence to support treatment of individual personality disorders led researchers to largely ignore specific DSM Axis II personality disorder categories and adopt a more parsimonious approach to treatment, focusing instead on dimensions of psychopathology that cut across various personality disorders. The limitations of categorical models led to the development of a trait-based algorithm initially proposed by [Siever and Davis \(1991\)](#) and further developed by [Soloff \(1998\)](#). This new algorithm posited that four dimensions cutting across all personality disorder categories— affective instability, anxiety-inhibition, cognitive-perceptual disturbances and impulsivity-aggression—should be studied rather than individual symptom clusters or diagnoses. This model has served as a dominant framework for understanding the evidence regarding medication effects on personality disorders ([Bateman et al. 2015](#)).

The diagnosis and classification of personality disorders are shifting toward a more dimensional model of classification ([Widiger and Simonsen 2005](#)). Although several models were proposed in DSM-IV-TR ([American Psychiatric Association 2000](#)), the model included in Section III of the recently published DSM-5 as an alternative to current categorical classifications is based on the empirically supported Five-Factor Model (FFM), which includes the following broad domains: negative affectivity (vs. emotional stability), detachment (vs. extraversion), antagonism (vs. agreeableness), disinhibition (vs. conscientiousness), and psychoticism (vs. lucidity) ([Widiger and Costa 1994](#)). This model, in contrast to other models, was felt to adequately cover the full range of personality disorder symptomatology and has amassed the most empirical support ([Widiger and Costa 1994](#)). Compared with other models, it was felt to more accurately reflect normal as well as abnormal personality functioning and to better account for the symptoms and traits of DSM-IV-TR personality disorders ([Clark 2007](#)). The aspects of personality functioning considered to be most important to people across all cultures and languages when they describe themselves and others pertain to interpersonal relatedness, a domain thought to form the core of personality disorders ([Pincus 2005](#)) and captured by the two factors of extraversion and agreeableness.

Despite the formidable challenges in understanding what constitutes “disordered” personality features and their optimal treatment approach, reasons for optimism exist. The traditional view that personality disorders are necessarily chronic, stable over time, and marked by poor outcomes has been challenged in recent years in light of the fact that the

more serious epiphenomena of disorders such as borderline personality disorder, including serious suicide attempts, impulsive behaviors, misuse of services, and aggressive outbursts, all show improvement with treatment. Findings from longitudinal studies of personality disorders such as the Collaborative Longitudinal Personality Disorders Study (CLPS) and the McLean Study of Adult Development (MSAD) have challenged the traditional entrenched pessimism about the poor prognoses of personality disorders such as borderline personality disorder (Gunderson et al. 2011; Zanarini et al. 2010). Such findings have driven the removal from DSM-5 of the separate Axis II category altogether, as well as the introduction of terms such as *remission* and *relapse* to the conceptualization of personality disorders.

---

## Pharmacotherapy for Cluster B Personality Disorders

---

Almost all of the clinical research trials examining medication treatments for personality disorders have studied borderline personality disorder (BPD). The symptom clusters typically targeted in this condition, although varying from trial to trial in how they are defined and assessed, are dysregulated impulsivity and aggression, affective lability and hyperreactivity, cognitive-perceptual disorganization, anxiety, and dissociation. Dysregulation of impulses and affective instability are widely viewed as the hallmark symptoms of BPD. Studies suggest that despite the limitations in our knowledge of treatments for BPD, drugs are very frequently prescribed, and polypharmacy is common (Bridler et al. 2015; Knappich et al. 2014; Zanarini et al. 2004b).

### Conventional Antipsychotics

Abnormalities in dopamine signaling are thought to underlie the cognitive-perceptual symptoms of BPD, which include paranoia, perceptual aberrations, and subtle thought disorder, and this understanding forms the rationale for the use of antipsychotics in the disorder. BPD patients have been found to have higher plasma and cerebrospinal fluid levels of the dopamine metabolite homovanillic acid, and dopamine receptor genetic polymorphisms have been found to interact with traumatic attachment stressors in producing the attachment insecurity and disorganization thought to be integral to BPD (Steele and Siever 2010). On the whole, studies with conventional antipsychotics suggest significant improvements in anger with haloperidol and in suicidality with flupenthixol decanoate, whereas effects on psychosis, irritability, and affective symptoms have been variable (Table 51-1). Any benefits of older antipsychotic agents must be weighed against these agents' well-established propensity to cause extrapyramidal symptoms (EPS) and tardive dyskinesia.

## Atypical Antipsychotics

Atypical antipsychotics have received increased attention in recent years (see [Table 51-1](#)). On the whole, BPD treatment studies using atypical antipsychotics have shown improvements in affective instability, impulsivity, psychosis, and interpersonal dysfunction. In clinical practice, it appears that atypical antipsychotics are prescribed more frequently than conventional agents due to their greater tolerability and lower risks of EPS and tardive dyskinesia. A number of studies have examined olanzapine in the treatment of BPD (see [Table 51-1](#)). The largest study to date was conducted by [Zanarini et al. \(2011\)](#). In this 12-week randomized, double-blind, placebo-controlled trial, 451 outpatients with DSM-IV ([American Psychiatric Association 1994](#)) borderline personality disorder received olanzapine 2.5 mg/day ( $n=150$ ), olanzapine 5–10 mg/day ( $n=148$ ), or placebo ( $n=153$ ). Olanzapine 5–10 mg/day showed a clinically modest advantage over placebo in the treatment of overall borderline psychopathology. Treatment-emergent adverse events included somnolence, fatigue, increased appetite, and weight gain ([Zanarini et al. 2011](#)). A 12-week open-label extension of the study found sustained improvements over longer durations ([Zanarini et al. 2012](#)). Another large-scale placebo-controlled study comparing the efficacy and tolerability of low and moderate dosages of extended-release quetiapine in 95 adults with BPD found that participants in the low-dosage quetiapine (150 mg/day) group had significant improvement on overall BPD severity measures compared with those in the placebo group. Eighty-two percent in the low-dosage quetiapine group were rated as “responders,” compared with 74% in the moderate-dosage (300 mg/day) group and 48% in the placebo group. The most common adverse events with quetiapine (which were more prominent in the high-dosage group) included sedation, changes in appetite, and dry mouth. The overall completion rate for the 8-week double-blind treatment phase was 67% (67% for the low-dosage quetiapine group, 58% for the moderate-dosage quetiapine group, and 79% for the placebo group) ([Black et al. 2014](#)).

## Antidepressants

Although older antidepressants including tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) have shown modest efficacy in improving affective symptoms in BPD ([Cornelius et al. 1993](#); [Cowdry and Gardner 1988](#); [Soloff et al. 1993](#)), both TCAs and

MAOIs pose serious risks in overdose and carry the potential for adverse events that are of particular concern in this unstable, impulsive population.

BPD studies with selective serotonin reuptake inhibitors (SSRIs) have yielded mixed findings. Whereas some older studies suggested statistically significant superiority of SSRIs over placebo in BPD (Coccaro and Kavoussi 1997; Markovitz 1995; Salzman et al. 1995), more recent controlled studies with SSRIs showed either no difference from placebo or additional benefit over placebo only when SSRIs were used to augment standard treatments such as dialectical behavior therapy (Simpson et al. 2004). SSRI monotherapy also has demonstrated no statistical benefit over atypical antipsychotic monotherapy for depression and impulsive aggression (Zanarini et al. 2004a).

BPD studies with serotonin-norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine (Markovitz and Wagner 1995) and the newer agent duloxetine (Bellino et al. 2010) also showed modest efficacy in treating affective symptoms (irritability, anger) and impulsive behaviors (self-injury), but these trials were limited by their open-label design and small sample sizes. Studies of antidepressant treatment in BPD are summarized in Table 51-2.

**TABLE 51-2. Summary of medication treatment trials with antidepressants in borderline personality disorder (BPD)**

## Mood Stabilizers

Mood stabilizers are known to calm excitatory neurotransmission, but the various agents differ in terms of their mechanism of action and effects on  $\gamma$ -aminobutyric acid (GABA)-ergic and glutamatergic signaling mechanisms. As a class, mood stabilizers have gained increasing attention as a medication strategy for treatment of BPD symptoms, demonstrating moderate effect sizes on impulsive aggression, affective instability, self-injurious behaviors, and overall functioning.

Early studies supported a role for lithium in BPD ([Rifkin et al. 1972](#)). In a single small controlled study ([Links et al. 1990](#)), 17 subjects with BPD received 6 weeks each of lithium, the TCA desipramine, and placebo in a randomized crossover design, and 10 subjects completed at least two medication trials. Neither medication was better than placebo for depressive symptoms, although lithium led to a significant decrease in anger and suicidality according to clinician but not patient perception.

Anticonvulsants are used more widely than lithium in the treatment of BPD symptoms. Early studies with carbamazepine reported mixed findings, with some showing improvement in behavioral dyscontrol ([Cowdry and Gardner 1988](#)) and others showing no significant improvement with carbamazepine treatment ([de la Fuente and Lotstra 1994](#)) compared with placebo.

More recently, anticonvulsant trials have focused on valproate and newer anticonvulsants. In one placebo-controlled trial, 16 outpatients with BPD were treated for 10 weeks with valproate or placebo ([Hollander et al. 2001](#)). Global improvement was significant by two measures in patients treated with valproate, but the small sample size and high dropout rate precluded statistically significant findings. In another controlled study, valproate's efficacy was examined in 30 women with comorbid BPD and bipolar II disorder over 6 months of treatment ([Frankenburg and Zanarini 2002](#)). Valproate at an

average dosage of 850 mg/day was well tolerated and resulted in significant improvement in interpersonal sensitivity, hostility/anger, and aggression compared with placebo.

A larger placebo-controlled multicenter trial of valproate showed some efficacy for impulsive aggression in Cluster B personality disorders (Hollander et al. 2003). In this study, 91 outpatients selected for the presence of prominent impulsive aggression and the absence of bipolar I disorder or current major depression were randomly assigned to 12 weeks of treatment with placebo or valproate (mean dosage of 1,400 mg/day). Valproate was well tolerated overall, with only 17% of subjects discontinuing because of valproate-related adverse events. The main finding of the study was a significant decrease in impulsive aggression in the last month of treatment, with valproate treatment reducing irritability, impulsive behaviors, and overall aggression, including verbal assault, assault against objects, and assault against others (Hollander et al. 2003).

Controlled studies have focused on lamotrigine (200 mg/day) and topiramate (200-250 mg/day) and suggest that both agents may offer therapeutic benefits in treating affective instability and impulsivity in BPD. Lamotrigine (at a target dosage of 200 mg/day) has demonstrated efficacy in treating impulsivity, affective symptoms, and aggression in BPD (Tritt et al. 2005). Long-term follow-up studies suggest that the benefits of lamotrigine are sustained and that it is an effective and relatively safe agent for longer-term treatment of aggression in women with BPD (Leiberich et al. 2008). Topiramate is another agent that has demonstrated efficacy for certain dimensions of BPD, such as anger (Loew et al. 2006; Nickel et al. 2004, 2005). Follow-up studies of topiramate support its efficacy long-term (Loew and Nickel 2008; Nickel et al. 2006).

BPD treatment trials with mood stabilizers are summarized in Table 51-3.

## Other Medications and Agents

Despite their widespread use, benzodiazepines on the whole are not recommended in the treatment of BPD due to their risk of worsening impulsivity and suicidality (Cowdry and Gardner 1988). Studies using the  $\alpha_2$ -adrenergic agonist clonidine showed efficacy in treatment of comorbid posttraumatic stress disorder (PTSD) and BPD (Ziegenhorn et al. 2009) and suggest a role for clonidine in the treatment of hyperarousal and sleep disturbances associated with BPD. Finally, several randomized controlled trials support the use of omega-3 fatty acids in reducing aggression and affective symptoms in patients with moderate to severe BPD (Zanarini and Frankenburg 2003).

## Neuropeptides and Other Future Directions for Research

Recent psychopharmacological research in patients with BPD has centered on neuropeptides, including the opioids, oxytocin, vasopressin, and neuropeptide Y, all of which modulate complex networks of neurotransmitter systems and facilitate coordination of affective signaling and behaviors. BPD has been conceptualized as being related to disturbed attachment, and thus oxytocin, vasopressin, and opioids may be of particular relevance for treating BPD, given the developmental role of these neuropeptides in attachment and the relationship between attachment security and stable social cognitive representations of self and other (Fonagy and Luyten 2009; Stanley and Siever 2010).

Although some studies have suggested a role for opiate antagonists in the treatment of dissociative symptoms and flashbacks in BPD (Bohus et al. 1999; Griengl et al. 2001), other trials have not demonstrated any benefit of opioid antagonist treatment on acute symptoms of tension and dissociation in BPD (Philipsen et al. 2004).

Another neuropeptide system that has received increased attention for drug intervention in the treatment of interpersonal dysfunction is the oxytocin system. Oxytocin is associated with empathic processing and affiliative bonding and has been shown to have attenuating effects on the hypothalamic-pituitary-adrenal axis and the autonomic nervous system. Oxytocin deficits have been linked to attachment insecurity and separation distress, and oxytocin plays a role in mediation of social cues, trust, and prosocial behavior (Bartz and Hollander 2006). Lower cerebrospinal fluid levels of oxytocin have been found in women with a history of childhood abuse or neglect (Heim et al. 2009), and early experimental studies suggest a role for the oxytocin system in attenuating emotional and hormonal responses to stress in BPD (Simeon et al. 2011).

Individuals with BPD have been found to lack psychophysiological and amygdala indicators of habituation to repeated interpersonal affective stimuli of positive or negative valence (Hazlett et al. 2012). Working through interpersonal experiences may be difficult for BPD patients, and adjunctive medication treatment that targets the capacity for habituation may optimize overall treatment efficacy. Habituation, a process dependent on neuroplasticity and changes in receptor density, is fundamentally affected by glutamatergic *N*-methyl-D-aspartate (NMDA) signaling, suggesting a role for glutamatergic medications in improving the affective, impulsive, interpersonal, and cognitive symptoms of BPD. Enhancement of learning and psychophysiological habituation modulated by NMDA signaling could synergize psychopharmacology and psychotherapy, analogous to strategies proposed for PTSD with respect to enhancement of fear extinction

and interference of traumatic memory consolidation (Grosjean and Tsai 2007; Ripoll 2013).

Endocannabinoid neurotransmission has been implicated in impulsivity (Pattij and Vanderschuren 2008), depression and suicidality (Vinod and Hungund 2006), and psychosis (Parolaro et al. 2010), possibly related to modulation in dopaminergic signaling (Fitzgerald et al. 2012). Both BPD and complex PTSD are powerfully associated with the experience of interpersonal violence during childhood and adolescence. These disorders frequently co-occur and often result in pervasive problems in emotion regulation and pain perception, processes that involve the endocannabinoid system. A recent study investigated serum levels of the endocannabinoids anandamide and 2-arachidonoylglycerol and related fatty acid ethanolamides (FAEs) in BPD patients, PTSD patients, and healthy control subjects. Significant alterations were found for both endocannabinoids in BPD and for the FAE oleoylethanolamide in PTSD, suggesting a respective link to both disorders (Schaefer et al. 2014).

There is evidence that cyclical hormone changes (e.g., higher progesterone levels in the luteal phase; estrogen fluctuations at ovulation and in the luteal phase) may affect the expression of BPD features among at-risk women (Eisenlohr-Moul et al. 2015). Finally, altered levels of inflammatory cytokines such as interleukin-6 (Coccaro et al. 2015), prolactin (Atmaca et al. 2015b), N-acetylaspartate (NAA) (Atmaca et al. 2015a), and cortisol (Rausch et al. 2015) have been linked with BPD and suggest putative neurobiochemical targets for future drug research.

## Conclusions and Treatment Guidelines for Cluster B Personality Disorders

In summary, several open and controlled pharmacological treatment trials of BPD have been conducted. Interpretation of the findings is somewhat complicated by the diversity of patient presentations at treatment entry, including inpatient or outpatient status; overall severity of baseline pathology; presence of comorbid personality disorders; presence or absence of major depressive disorder, including atypical symptoms; emphasis on varying symptomatology, such as psychoticism or impulsive aggression; and use of a wide range of outcome measures. In addition, some of the core features of the disorder, such as identity diffusion, interpersonal vicissitudes, and primitive defensive structure, were never examined, and therefore the assumption that these features are less medication responsive has not been empirically proven. On the basis of the existent algorithms in the literature, modified according to the results of the latest medication trials, we propose a medication treatment approach for BPD (Table 51-4).

**TABLE 51-4. Psychopharmacological treatment guidelines for borderline personality disorder**

**If the most prominent symptoms are depression, interpersonal sensitivity, and impulsivity and aggression:**

1. Start with selective serotonin reuptake inhibitor (SSRI) (or related antidepressant).
2. *If good response*, maintain.  
*If partial response*, add mood stabilizer.  
*If no response*, switch to mood stabilizer.
3. *If significant residual anger, anxiety, or dyscontrol*, add atypical antipsychotic.

**If the most prominent symptoms are mood lability, impulsivity and aggression, and family history of bipolar spectrum:**

1. Start with mood stabilizer (valproate; carbamazepine or lithium as alternatives).
2. *If good response*, maintain.  
*If partial response*, add mood stabilizer.  
*If no response*, switch to mood stabilizer.

3. *If significant residual anger, anxiety, or dyscontrol*, add atypical antipsychotic.

**If the most prominent symptoms are paranoia, psychoticism, hostility, and overwhelming anxiety:**

1. Start with atypical antipsychotic (olanzapine and risperidone most studied).
  2. *If good response*, maintain.  
*If partial response*, add SSRI or mood stabilizer.  
*If no response and minimal mood symptoms*, switch to typical antipsychotic.
- 

In almost all Cluster B personality disorder trials, BPD has been the primary focus. Although some of these trials, as individually mentioned in the overview above, included mixed samples of Cluster B participants, they did not present separate analyses for non-BPD diagnoses. Therefore, the general principle to follow in treating Cluster B disorders other than BPD would be to target symptom clusters with medications as per the guidelines developed for BPD (see [Table 51-4](#)). In general, narcissistic and histrionic personality disorders are not characterized by the severe degree of either mood lability or impulse dyscontrol seen in BPD, but for individuals in whom such features are more prominent or problematic, medication trials can be attempted.

In regard to antisocial personality disorder, the general treatment guideline is that individuals who meet full criteria for the disorder are generally treatment noncompliant and nonresponsive. Very few pharmacological studies have focused on patients with antisocial personality disorder ([Coccaro 1993](#)). Early trials suggested a role for lithium in reducing markers of antisocial behavior, including rule infractions and impulsive-aggressive behavior, among incarcerated males ([Wickham and Reed 1987](#)). Studies with phenytoin 300 mg/day among prisoners and outpatients also showed some benefit for impulsive (but not premeditated) behaviors as well as reduced measures of anxiety and depression ([Stanford et al. 2001](#)). Finally, there is some evidence of benefit from nortriptyline (25-75 mg/day) and bromocriptine (15 mg/day) ([Powell et al. 1995](#)) in reducing alcohol abuse among individuals with antisocial personality disorder, a significant finding in light of the fact that men with antisocial personality disorder have been found to be three to five times more likely than those without the disorder to abuse alcohol and illicit drugs ([Robins and Price 1991](#)).

More recently, a report on four antisocial personality disorder inpatients in a maximum-security facility found decreases in impulsivity, hostility, aggressiveness, irritability, and rage reactions with quetiapine treatment at dosages of 600-800 mg/day ([Walker et al. 2003](#)). Generally, borderline patients who have some antisocial traits are more responsive to medication treatment than are purely antisocial patients. Studies with the mood stabilizer valproate suggested that individuals with antisocial personality disorder were less responsive to the pharmacotherapy than were subjects with other Cluster B personality disorders ([Hollander et al. 2003](#)). It has also been found, however, that borderline patients are significantly more likely than antisocial personality disorder patients to have received adequate medication trials with anxiolytics and antidepressants ([Zanarini et al. 1988](#)).

---

## Pharmacotherapy for Cluster A Personality Disorders

---

The main symptoms of Cluster A personality disorders—cognitive and perceptual distortions—are reminiscent of both the positive and the negative symptoms of schizophrenia, and dopaminergic dysregulation has been postulated to underlie these symptoms ([Siever and Davis 1991](#)). Schizotypal personality disorder is by far the most extensively investigated disorder of the cluster in terms of biological underpinnings ([Siever 1985](#); [Siever et al. 1990](#)), relation to DSM-IV Axis I as a schizophrenia spectrum disorder ([Asarnow et al. 2001](#); [Kendler et al. 1994](#)), and pharmacological treatment trials. Similar to schizophrenia patients, patients with schizotypal personality disorder (SztPD) often demonstrate cognitive processing deficits, structural functioning abnormalities, and other physiological abnormalities ([McClure et al. 2007](#)). Some studies have reported greater preservation of frontal volume in patients with SztPD ([Siever and Davis 2004](#)) compared with patients with schizophrenia. Functional magnetic resonance imaging (fMRI) data point to abnormal caudate volumes in SztPD patients, with associated cognitive deficits in working memory, implicating striatum dysfunction, and associated abnormalities in cortical-subcortical circuits may play a key role in disorders of cognition and behavior such as SztPD ([Levitt et al. 2004](#)).

[Serban and Siegel \(1984\)](#) treated a sample of patients, one-third of whom had SztPD and one-third of whom had SztPD and BPD, with either thiothixene or haloperidol, without placebo, and found marked improvement in psychotic spectrum symptoms. [Goldberg et al. \(1986\)](#) treated a sample of outpatients with BPD and/or SztPD with thiothixene or placebo and found a significant improvement in psychotic symptoms with thiothixene that was more pronounced in the patients with SztPD. [Soloff et al. \(1986, 1989\)](#), in a sample containing a sizable proportion of patients with combined SztPD and BPD, found haloperidol to be superior to placebo in the treatment of schizotypal symptoms but failed to replicate this finding in a later study ([Soloff et al. 1993](#)), possibly due to lower severity of symptoms in the second study.

[Schulz et al. \(1999\)](#) reported improvement in psychotic symptoms in a small group of patients who received olanzapine, most of whom had SztPD that was comorbid with BPD. There is one published randomized, placebo-controlled trial of an atypical antipsychotic (risperidone 0.25–2.0 mg/day) focusing exclusively on SztPD, which found risperidone to be significantly more efficacious than placebo ([Koenigsberg et al. 2003](#)).

The evidence for use of antidepressants in treatment of SztPD symptoms was weak and at times contradictory, with only a few open-label studies demonstrating some improvement in impulsive aggression, self-injurious behaviors, and depressive and psychotic symptoms with the SSRI fluoxetine ([Coccaro and Kavoussi 1997](#); [Markovitz et al. 1991](#)) and other studies showing detrimental effects (worsening of hostility and paranoia) with the TCA amitriptyline ([Soloff et al. 1986, 1989](#)).

Randomized controlled trials have shown improved cognitive performance on neuropsychological tasks with pergolide, a dopaminergic agonist active at both the D<sub>1</sub> and the D<sub>2</sub> receptor ([McClure et al. 2010](#)), and the noradrenergic  $\alpha_{2A}$  agonist guanfacine ([McClure et al. 2007](#)). Research on the neurobiological substrates of social cognitive dysfunction (empathic deficits, relational paranoia, and social isolation in SztPD) may provide future targets for pharmacotherapeutic intervention.

---

## Pharmacotherapy for Cluster C Personality Disorders

---

Anxiety and behavioral inhibition are the main symptoms that characterize individuals with Cluster C personality disorders, although the focus of the anxiety varies across disorders. The anxiety centers on social interaction in avoidant personality disorder, need for control of uncertainty in obsessive-compulsive personality disorder, and conflicts surrounding autonomy in dependent personality disorder.

Limited data suggest a role for the MAOI phenelzine ([Deltito and Perugi 1986](#); [Liebowitz et al. 1988](#)) and the SSRI fluoxetine ([Deltito and Stam 1989](#)) in the treatment of avoidant personality disorder. However, in all of these studies, most, if not all, of the avoidant subjects had comorbid social phobia, and the criteria used to differentiate the two conditions and their medication response were not clearly defined. In a more systematic approach, [Reich et al. \(1989\)](#) openly treated 14 patients with DSM-III-R ([American Psychiatric Association 1984](#)) social phobia with alprazolam for 8 weeks at a mean daily dosage of 3 mg and specifically measured treatment response in nine avoidant personality traits based on the DSM-III-R diagnostic criteria for avoidant personality disorder. Six of the nine avoidant traits showed significant improvement during treatment, correlating with a change in subjective anxiety and disability.

[Greve and Adams \(2002\)](#) reported anecdotal evidence for the anticonvulsant carbamazepine in the treatment of irritability and hostility associated with obsessive-compulsive personality disorder ([Greve and Adams 2002](#)). Although overlap with DSM-IV Axis I obsessive-compulsive disorder was suggested by previous findings of a familial spectrum of obsessive-compulsive disorder and obsessive-compulsive personality disorder ([Samuels et al. 2000](#)) and the clinical observation that both disorders exhibit compulsive behaviors, more recent data are emerging that support separation of the two as distinct clinical entities, differentiable on the basis of obsessions in obsessive-compulsive disorder versus excessive capacity to delay reward in obsessive-compulsive personality disorder ([Pinto et al. 2014](#)).

---

## Conclusion

---

In this chapter we reviewed the pharmacological treatment of personality disorders, providing a conceptual framework, highlighting methodological limitations, and summarizing medication treatment trials to date. Almost all of these trials focused on symptom clusters, such as psychoticism, impulsivity, hostility/aggression, mood instability, and anxiety/inhibition. This focus is consistent with the growing conceptualization of personality disorders as syndromes of overlapping traits arising from a complex interaction between genetic determinants and developmental processes, influenced by adverse life events, with the primary manifestations of the disorder represented as difficulties with interpersonal relationships. Translation of current research into robust clinical recommendations for the treatment of personality disorders has been hampered by a number of methodological limitations, including heterogeneity of study populations, selective attention to BPD, and diversity of outcome measures. Despite these limitations, there is sufficient evidence to suggest a role for medications as an adjunctive treatment for symptom reduction, functional improvement, and overall adaptation for personality disorders. Progress in our understanding of the neurobiological underpinnings of

personality and their component dimensions will help guide development of better models of personality and its disordered forms, thereby providing a basis for rational pharmacotherapy to complement psychosocial interventions.

## CHAPTER 52

# Treatment of Eating Disorders

W. Stewart Agras, M.D.

Eating disorders—anorexia nervosa (AN), bulimia nervosa (BN), and binge-eating disorder (BED)—have a combined prevalence in women of 3%–6%, taking into account the diagnostic changes in DSM-5 ([American Psychiatric Association 2013](#); [Hudson et al. 2007](#); [Mond 2013](#)). About 10% of all cases of AN and BN are in males, with the proportion rising to about 30% for BED in clinical samples. Because much comorbid psychopathology is associated with each of these disorders, including current major depression in about 25% of cases, the treatment plan must take any such disorders into account. Both psychopharmacological and psychotherapeutic treatments are effective for BN and BED. Hence, determining how to sequence or combine treatment modalities is an important issue. Cases of BN (and BED) were rarely seen until their increase throughout the Western world in the late 1970s

([Garner et al. 1985](#)). This increase has been attributed to increasing societal pressures on women to maintain a thin body shape.

Research on the psychopathology and treatment of the eating disorders was relatively slow to develop compared with research in the depressive and anxiety disorders. This delay was likely attributable to the low prevalence of AN and the relatively recent increase in the number of cases of BN. Moreover, BED was not officially recognized as a disorder until DSM-5 ([American Psychiatric Association 2013](#)), although there is now a large body of literature on the condition. Despite this slow start, sufficient controlled treatment trials are now available to provide guidance to the clinician.

---

## **Bulimia Nervosa**

---

BN has its onset in adolescence or early adult life, with a prodromal period characterized by dissatisfaction with body shape and a fear of becoming overweight, followed by dietary restriction and weight loss. Sooner or later, periods of dietary restriction are followed by episodes of binge eating experienced as a loss of control over dietary intake. These, in turn, further aggravate dissatisfaction with body shape and fears of weight gain. Ultimately, the bulimic patient discovers purging, usually in the form of self-induced vomiting, with or without laxative or diuretic use, excessive exercise, or (less commonly) fasting; and in rare cases in the form of chewing food and spitting it out.

Medical complications of BN include potassium depletion, which combined with low weight may lead to cardiovascular

complications and death. Other complications include dental caries, salivary gland enlargement, and exercise injuries ([Mitchell and Crow 2010](#)). Comorbid psychopathology includes major depression; anxiety disorders, social phobia, and panic disorder; obsessive-compulsive disorder; alcoholism; and personality disorders, particularly those in the Cluster B spectrum.

## Pharmacological Treatment

### Antidepressants

The use of antidepressants in the treatment of BN was sparked by the observation that depression is often a comorbid feature of the disorder ([Pope and Hudson 1982](#)). In 1982, two groups of researchers conducted small-scale uncontrolled studies indicating that both tricyclic antidepressants and monoamine oxidase inhibitors reduced binge eating and purging ([Pope and Hudson 1982](#); [Walsh et al. 1982](#)). A wide range of antidepressants have been found effective in double-blind, placebo-controlled studies, including imipramine ([Agras et al. 1987](#); [Mitchell et al. 1990](#); [Pope et al. 1983](#)), desipramine ([Agras et al. 1991](#); [Barlow et al. 1988](#); [Blouin et al. 1989](#); [Hughes et al. 1986](#)), phenelzine ([Walsh et al. 1988](#)), brofaromine ([Kennedy et al. 1993](#)), trazodone ([Pope et al. 1989](#)), fluoxetine ([Fluoxetine Bulimia Nervosa Collaborative Study Group 1992](#)), fluvoxamine ([Milano et al. 2005](#)), and citalopram ([Leombruni et al. 2006](#)). Fluoxetine is the only medication approved by the U.S. Food and Drug Administration (FDA) for the treatment of BN. Antidepressants are prescribed for BN at the same dosages used for treating depression, with the exception of fluoxetine, for which a dosage of 60 mg/day

was found more effective than 20 mg/day in reducing binge eating and purging in a placebo-controlled trial involving 387 bulimic women ([Fluoxetine Bulimia Nervosa Collaborative Study Group 1992](#)).

Overall, most antidepressants appear effective for the short-term treatment of BN, with little difference between them ([Hay and Claudino 2010](#)). Less is known about the long-term effectiveness of medication. In an early study ([Fichter et al. 1991](#)), 72 patients with BN successfully treated as inpatients were randomly assigned to receive either fluvoxamine or placebo. Those on the active drug had a higher rate of recovery over a 15-week period. In a second study of this issue, 147 women with BN who had decreased their vomiting by at least 50% while taking 60 mg of fluoxetine over an 8-week period were randomly allocated to continue medication or to be switched to placebo ([Romano et al. 2002](#)). A survival analysis found that the group receiving active medication experienced a longer time to relapse (or dropout) than did the placebo group. However, it should be noted that at the 12-month follow-up, 83% of the fluoxetine group and 92% of the placebo group had relapsed or dropped out. The authors suggest that given these results, a multimodal approach to the treatment of BN, including cognitive-behavioral therapy (CBT), should be considered.

To date, only one study has compared different lengths of antidepressant treatment, in this case with desipramine. Patients with BN treated for 16 weeks relapsed to pretreatment levels of binge eating when medication was withdrawn. On the other hand, those treated for 24 weeks maintained remission after withdrawal and at 1-year follow-up ([Agras et al. 1991, 1994](#)). This study suggests that patients who respond to antidepressant treatment should

be given a minimum trial of 6 months on medication. For the most part, however, controlled studies of antidepressants are of relatively short duration, as is the assessment of bulimic symptoms. Both of these factors may somewhat exaggerate the clinical efficacy of these medications.

In a study involving 77 BN patients ([Walsh et al. 2006b](#)) that examined the rate of decline in bulimic symptoms with desipramine, the authors found that patients unlikely to respond to the antidepressant could be reliably identified after 2 weeks of treatment. This finding was replicated in a combined data set ( $N=785$ ) from two controlled trials ([Sysko et al. 2010](#)). Patients who did not reduce binge eating or vomiting by 60% by week 2 of treatment were unlikely to respond to fluoxetine. Identification of poor responders early in treatment allows for the deployment of different approaches to treatment.

One problem with medication given at times other than bedtime is that a significant amount may be purged through subsequent vomiting. Side effects and reasons for discontinuation of the various medications are similar to those observed in the treatment of depression. However, a study of bupropion found that a higher-than-expected proportion of bulimic patients developed grand mal seizures ([Horne et al. 1988](#)). The authors concluded that bupropion should not be used for the treatment of BN.

## **Antiepileptics**

Although considerable evidence from controlled trials indicates that most antidepressants are useful in the treatment of BN, few controlled studies of other pharmacological agents with a reasonable sample size have appeared in the literature. However, topiramate (an

anticonvulsant drug) has been evaluated in two controlled trials. The reason for considering topiramate was that epileptic patients experienced appetite reduction and weight loss on this medication. In the first study ([Hoopes et al. 2003](#)), patients meeting criteria for DSM-IV-TR ([American Psychiatric Association 2000](#)) bulimia nervosa were allocated at random to treatment with either topiramate at an average dosage of 100 mg/day ( $n=35$ ) or placebo ( $n=34$ ) over a 10-week period. Twenty-two (63%) of those in the topiramate group completed the trial, and topiramate was statistically superior in reducing binge eating and purging, with 22% of completers in remission at the end of treatment. In the second study ([Nickel et al. 2005](#)), 30 patients with BN were randomly allocated to receive either topiramate or placebo. Topiramate was statistically superior to placebo in reducing binge eating and purging; however, no data on remission or recovery were reported. Side effects commonly seen with topiramate are fatigue, cognitive blunting, and flu-like symptoms.

## Combined Treatment

CBT for BN developed in parallel with the use of antidepressants. CBT is considered the first-line treatment for BN because it appears to be more effective than antidepressant medication and other psychotherapies such as interpersonal psychotherapy ([Hay and Claudino 2010](#)). There is also evidence for the effectiveness of guided self-help CBT. The components of CBT include psychoeducation about BN; reduction of dieting and reinstatement of normal eating; exposure to feared foods; reduction of concerns about weight and shape; and reduction of interpersonal

triggers of binge eating. The existence of two different and effective treatments, antidepressant medications and CBT, naturally led to the question of whether the combined treatments would be more effective than either treatment alone.

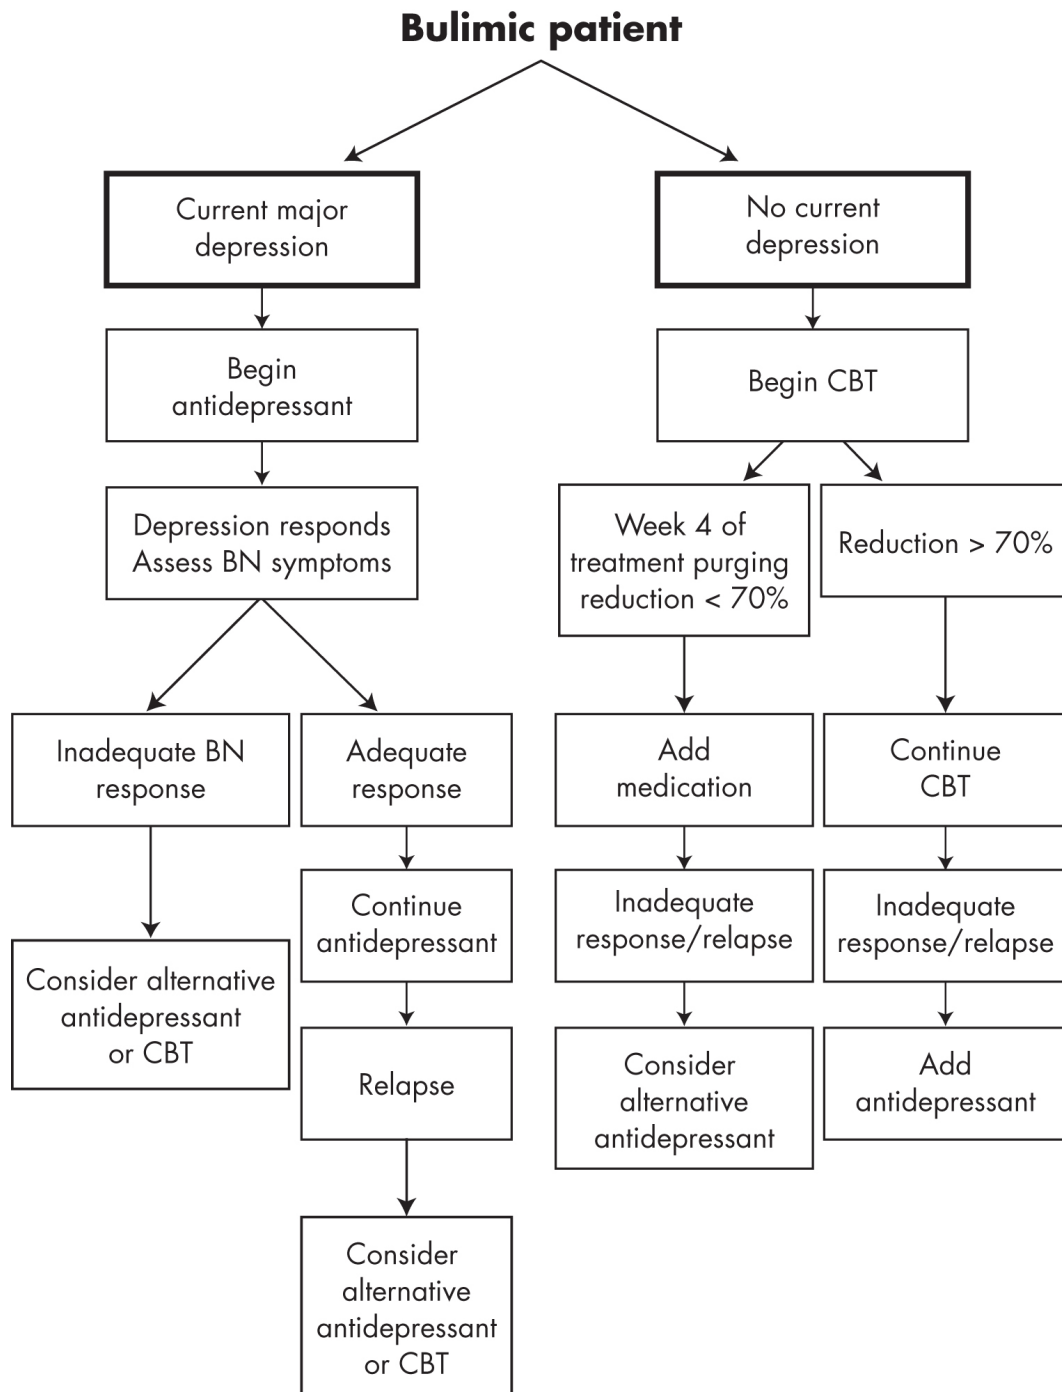

The largest study of combined treatment conducted to date, which involved 120 women with BN, used a medication regimen consisting of desipramine followed by fluoxetine if the first medication was either ineffective or poorly tolerated ([Walsh et al. 1997](#)). It is important to note that the two-medication combination was used by two-thirds of the patients assigned to active medication, suggesting that a two-medication combination is closer to clinical reality than the use of a single medication. The average dosage of desipramine was 188 mg/day, and that of fluoxetine was 55 mg/day. Forty-three percent of the patients receiving medication dropped out of the study, compared with 32% of those receiving psychotherapy. Patients receiving active medication (in combination with CBT) had a significantly greater reduction in binge eating compared with those receiving placebo. Finally, antidepressant medication combined with CBT was superior to medication alone in reducing purging frequency. Among patients receiving CBT plus medication, 50% were in remission at the end of treatment, compared with 25% of those receiving medication alone. These findings suggest that the combination of CBT plus antidepressant medication may be the most effective approach to the treatment of BN.

## Comprehensive Treatment

Patients with BN should be treated as outpatients unless there are medical or psychiatric reasons for hospitalization (e.g., an intercurrent physical illness or a comorbid psychiatric disorder requiring hospitalization, such as major depressive disorder with suicidality). One reason that outpatient treatment is useful for the BN patient is that gains made in the hospital may not carry over to the patient's home environment, where more complex food stimuli and greater stress are present than in the hospital.

The research evidence to date suggests that the combination of antidepressant medication and CBT is likely to be somewhat more effective than either therapy alone. Because CBT is more effective than antidepressant medication and is associated with fewer dropouts than medication, in the ideal case, CBT should be the first therapy offered to the patient. However, CBT is not always available, and in such circumstances, medication will be the only choice. In addition, patient preferences for one or the other treatment should be taken into account.

The flow chart in [Figure 52-1](#) presents an algorithm as guidance to the overall treatment of BN. The first decision to make is whether the patient has current major depression, which is seen in approximately 25% of bulimic patients presenting for treatment. Because depressive symptoms can interfere with the conduct of CBT for BN, antidepressant medication should precede CBT in such patients. When the patient has sufficiently recovered from depression, the eating disorder should be reevaluated. If the patient has not recovered from the eating disorder, then CBT should be added.

**FIGURE 52-1.** Flow chart depicting different treatment sequences for bulimia nervosa (BN). CBT=cognitive-behavioral therapy.

As shown in [Figure 52-1](#), if patients without concurrent depression show less than a 70% reduction in purging with CBT after 4 weeks (six sessions) of therapy, an antidepressant should be added. This algorithm is based on the findings of a multisite study involving 194 women with BN, which found that the initial treatment response to CBT predicted outcome reasonably well ([Agras et al. 2000](#)). Patients experiencing less than a 70% reduction in purging after 4 weeks of treatment were more likely to be nonresponders. If there is inadequate response to antidepressant treatment or a relapse, an alternative antidepressant should be used. For patients who complete CBT with insufficient improvement despite having reduced their purging at session 6, an antidepressant should be advised.

---

## Binge-Eating Disorder

---

Although the association between binge eating and obesity had been noted from time to time, it was not until the upsurge of research into the psychopathology and treatment of BN that systematic attention was paid to BED. The principal features of BED are episodes of binge eating at a frequency of at least 1 day per week for 3 months, marked distress caused by binge eating, and binge eating that does not occur during the course of BN or AN ([American Psychiatric Association 2013](#)). Purging does not occur in this condition, although about 10% of patients with BED have a history of BN.

Between 1% and 3% of women in the general population meet criteria for BED ([Hudson et al. 2007, 2012](#)), a

proportion that is little changed by the new DSM-5 criteria, which—like those for BN—now require an average of one binge episode per week over a 3-month period. In clinical populations, the ratio of women to men with BED is approximately 3:2, the highest rate for men of any eating disorder. Although obesity is not a requirement for the diagnosis of BED, there is a substantial overlap between BED and obesity. Studies have shown that about one-quarter of obese individuals have symptoms that meet criteria for BED, and that the prevalence of binge eating increases as body mass index increases ([Marcus et al. 1985](#); [Spitzer et al. 1993](#); [Telch et al. 1988](#)). Because binge eating often precedes the onset of overweight, binge eating may be a risk factor for obesity. Moreover, BED is associated with comorbid psychopathology similar to that seen in BN and causes much distress; hence, it is an entity deserving of treatment in its own right. A comparison of individuals with BED with weight-matched non-binge-eating obese individuals found that subjects with BED were significantly more likely than those without BED to receive a diagnosis of major depressive disorder (51%), panic disorder (9%), or borderline personality disorder (9%) ([Yanovski et al. 1993](#)).

## Pharmacological Treatment

### Antidepressants

Double-blind, placebo-controlled studies suggest that antidepressants are at least as useful in the treatment of BED as they are in BN. Early placebo-controlled studies found desipramine to be effective in reducing binge eating, with an abstinence rate of 60% ([McCann and Agras 1990](#)). Studies of selective serotonin reuptake inhibitors (SSRIs)

have suggested moderate efficacy, with overall remission rates of approximately 40%, compared with 20% for placebo ([Appolinario and McElroy 2004](#); [McElroy et al. 2010](#)). Most studies showed some degree of weight loss, which for the most part was not clinically significant.

## **Antiepileptics**

Anticonvulsants such as topiramate and zonisamide also appear to be useful in the treatment of BED ([McElroy et al. 2006](#)). A 16-week double-blind multisite study in which 394 participants with BED were allocated at random to receive either topiramate or placebo provided evidence for the efficacy of topiramate ([McElroy et al. 2007](#)). The median dosage of topiramate was 300 mg/day. Dropouts were equivalent between groups (29% topiramate; 30% placebo). Fifty-eight percent of subjects in the topiramate group and 29% of those in the placebo group were in remission at the end of the study period. The mean weight loss was 4.5 kg in the topiramate group versus a small weight gain in the placebo group. The most common side effects specific to topiramate were paresthesia and difficulty concentrating. Hence, topiramate leads to a reasonable rate of remission of the eating disorder combined with substantial and clinically meaningful weight loss.

## **Other Medications**

A recent multisite study suggested that lisdexamfetamine, a dextroamphetamine-like drug FDA approved for the treatment of attention-deficit/hyperactivity disorder, may be useful, at least in the short term, for the treatment of BED ([McElroy et al. 2015](#)). Two hundred sixty individuals with BED were randomly allocated to receive active drug (30,

50, or 70 mg/day) or placebo. Exclusion criteria resulted in a group of subjects with very little comorbid psychopathology; hence, results relate only to this subgroup of BED patients. Lisdexamfetamine was administered for 8 weeks with a 1-week follow-up after discontinuation. Results were in favor of medication, with 50% of patients in the group receiving lisdexamfetamine 70 mg/day achieving 4 weeks without binge eating prior to the end of treatment, compared with 21.3% of patients on placebo. Results for patients receiving 50 mg/day were similar to those for the 70-mg/day group, but there was no difference between medication and placebo for the 30-mg/day group. Mean weight loss was 4.3 kg for the high-dosage group, compared with no loss for the placebo group. These results are encouraging both for binge-eating reduction and for weight loss, although long-term studies are now needed to examine maintenance of therapeutic gains and to extend the findings to a more representative group of patients.

A placebo-controlled study in 50 overweight participants with BED compared orlistat (a lipase inhibitor), given at a dosage of 120 mg three times daily, with placebo, both groups also receiving an abbreviated form of CBT ([Grilo et al. 2005](#)). At the end of treatment, 64% of those in the orlistat group and 36% of those in the placebo group were in remission. The proportions achieving at least a 5% weight loss were 36% for orlistat and 8% for placebo. However, after discontinuation of both treatments, there was no difference in abstinence rates between groups (52% in both groups).

Although in earlier studies the serotonin-norepinephrine reuptake inhibitor sibutramine appeared to be successful in reducing both binge eating and weight, it is no longer

available in the United States because of associated cardiovascular effects ([Grilo et al. 2014](#)).

## Comprehensive Treatment

BED presents three problems to the clinician: binge eating, overweight, and comorbid psychopathology, particularly depression. Hence, comprehensive treatment should address all of these problems. There are few direct comparisons of psychotherapy and medication, and the situation is further complicated by the larger placebo responses found in BED as compared with BN, possibly accounting for the lack of efficacy of pharmacological agents in smaller-scale studies. For patients who prefer medication, current evidence suggests that topiramate has the most evidence for efficacy in reducing binge eating and weight, although acceptability may be low due to side effects. Lisdexamfetamine may provide an additional effective approach to treatment focused on reducing binge eating. However, lisdexamfetamine is a Drug Enforcement Administration-controlled medication with potential for abuse and dependence; therefore, careful monitoring of dosage and vigilance for signs of misuse are needed. Less is known about medications that may add to the effects of psychotherapies such as CBT and interpersonal therapy, both of which are associated with substantial reductions in binge eating that appear to be well maintained, although weight losses are small. Hence, augmentation studies are needed to guide clinical decision making. However, consideration might be given to combining a weight-reducing agent with one of the effective psychotherapies.

---

# Anorexia Nervosa

---

AN is a relatively rare disorder characterized by marked weight loss, intense fear of gaining weight, and disturbance in the experience of body shape (i.e., feeling fat despite marked weight loss). It is the most lethal psychiatric disorder. A meta-analysis of 41 cohorts from peer-reviewed studies published between 1966 and 2010 found that AN patients were 5.2 times more likely to die prematurely than females in the general population and 18.1 times more likely to die by suicide ([Keshaviah et al. 2014](#)). Because of the disabling nature and chronicity of the condition and the lack of evidence-based treatments for the chronic form of the disorder, it has become apparent that identification and treatment of the disorder early in its course are essential.

A specific family therapy (family-based treatment [FBT]) for adolescents that aims to help parents take charge of their child's eating appears to be successful in both the short and the long term, with about 50% of adolescent patients with anorexia recovered both at the end of treatment and at follow-up ([Lock et al. 2005, 2010](#)). In the largest trial to date ([Agras et al. 2014](#)), 164 adolescents with AN were randomly allocated to either FBT or systems family therapy (SyFT). There were no statistically significant differences in outcome at either end-of-treatment or 1-year follow-up, with 40% recovering with FBT. However, FBT produced significantly faster weight gain early in treatment, which may have led to fewer hospitalizations than SyFT and hence to lower treatment costs (FBT \$8,963, SyFT \$18,005). Therefore, for adolescent AN, family therapy in general and FBT in particular are evidence-based treatments ([Hay et al. 2014](#)).

# Pharmacological Treatment

Controlled pharmacological studies in both adolescents and adults have generally shown a lack of efficacy. Most studies of antipsychotic agents in the treatment of AN, including chlorpromazine, pimozide, sulpiride, olanzapine, and risperidone, showed no evidence of efficacy for weight gain ([Dally and Sargant 1960](#); [Hagman et al. 2011](#); [Kafantaris et al. 2011](#); [Vandereycken 1984](#); [Vandereycken and Pierloot 1982](#)). Similarly, antidepressants have proved disappointing ([Mitchell et al. 2013](#)). An inpatient study found that fluoxetine was not effective in hospitalized patients with AN ([Attia et al. 1998](#)). In this study, 31 women hospitalized with AN participated in a 7-week randomized, double-blind trial of fluoxetine at a mean dosage of 56 mg/day. Four patients in each group terminated the trial early. Although all patients in the study showed improvement, no significant differences were seen between active medication and placebo. In addition, there was no apparent effect of medication on depression or obsessional symptoms. This study suggested that fluoxetine had no effect over and above that of an inpatient program and adds to the literature's consistent failure to show a beneficial effect of antidepressant medication during the period of weight regain.

Despite promising findings in an earlier small-scale outpatient study ([Kaye et al. 2001](#)), a double-blind, placebo-controlled trial in 93 adult outpatients found no benefit for fluoxetine in either promoting weight maintenance or prolonging time to relapse ([Walsh et al. 2006a](#)). As is usual in this population, a large proportion of patients dropped out or terminated early from treatment (51% of fluoxetine-treated and 63% of placebo-treated patients). A fairly high

proportion of patients were dissatisfied with treatment. The very high dropout rates make statistical comparisons between groups difficult because of the large amount of data being carried forward in an intent-to-treat analysis. Nonetheless, the only difference between groups was a statistical advantage for fluoxetine in reducing anxiety levels.

Given the finding that fluoxetine confers no benefit for adult patients with AN either during the weight-gain period in the hospital or during outpatient treatment, one must conclude that use of fluoxetine is not indicated in the treatment of AN except to treat comorbid psychopathology. However, there have been no satisfactory studies of other SSRIs in adolescents with AN, and such studies would appear warranted, given the high priority for treatment early in the course of AN.

Most patients with AN can be treated as outpatients. However, treatment can be difficult because of the patient's reluctance to gain weight. Weight should be monitored at every outpatient visit, and it is important that weight be measured in a hospital gown to prevent the use of lead weights to which some patients with anorexia resort. Other methods of inflating weight are less easy to detect, such as drinking large quantities of water before being weighed. Indications for hospitalization include weight less than 75% of ideal body weight for age and height, heart rate below 40 beats/minute, blood pressure below 90/60 mm Hg, potassium levels below 3 mEq/L, temperature below 97°F, and very rapid weight loss. In addition, because of the associated psychopathology in this disorder, the usual indications for hospitalization for severe psychopathology should be followed.

---

## Conclusion

---

The place of psychopharmacological agents in the treatment of BN has been well worked out. Treatment with sequential trials of different antidepressants should result in abstinence rates of about 40%. The addition of CBT enhances the effectiveness of antidepressants. It is becoming clear that agents such as topiramate and similar anticonvulsants are useful in the treatment of BED, with the added advantage of facilitating substantial weight loss in the overweight patient. The recent FDA approval of lisdexamfetamine dimesylate recognizes the potential benefit of this medication in BED. In the case of AN, there is little evidence that pharmacological agents are helpful in either inpatient or outpatient treatment of the adult patient, except to treat comorbid psychiatric disorders. There is insufficient information regarding adolescent AN to provide guidance regarding the use of medication at this point.

## CHAPTER 53

# Treatment of Insomnia

Andrew D. Krystal, M.D., M.S.

**Disturbances** of sleep occur at some point in the life of essentially everyone. However, the presence of a clinically significant insomnia disorder requires that the sleep disturbance meet a specific set of criteria: 1) there is a complaint of difficulty falling asleep or staying asleep; 2) this complaint is associated with clinically significant distress and/or daytime functional impairment; 3) these difficulties occur despite an adequate opportunity for sleep; and 4) the sleep disturbance is present for three or more nights per week for at least 3 months ([American Academy of Sleep Medicine 2014](#); [American Psychiatric Association 2013](#); [Krystal 2007](#)).

Available research suggests that insomnia disorder has a population prevalence of approximately 10% and is associated with impairments in quality of life; accidents; falls in the elderly; inability to function; increased risk of hypertension; and increased risk of major depressive disorder, anxiety disorders, suicidality, and substance-related disorders ([Avidan et al. 2005](#); [Baglioni et al. 2011](#); [Bathgate et al. 2016](#); [Breslau et al. 1996](#); [Ford and Kamerow 1989](#); [Harvey 2008](#); [Johnson et al. 2000](#); [Kessler et al. 2012](#); [Koski et al. 1998](#); [Léger et al. 2008](#); [Morin et al. 2011](#); [Ohayon 2002](#); [Ohayon and Reynolds 2009](#); [Roth et al. 2011](#); [Stone et al. 2014](#); [Vgontzas et al. 2013](#); [Winsper and Tang 2014](#)). Insomnia disorder most often occurs along with psychiatric and medical conditions ([Ford and Kamerow 1989](#); [Sarsour et al. 2010](#)). For many years, insomnia, especially when chronic, was assumed to be a symptom of these conditions ([National Institutes of Health 1984, 2005](#)). On this basis, directing treatment specifically to chronic insomnia was discouraged. Instead, it was recommended that treatment be administered for the associated medical and psychiatric conditions under the assumption that the insomnia would improve along with the other symptoms of the medical-psychiatric condition ([National Institutes of Health 1984, 2005](#)). Over time, the accumulating evidence suggested that this model is fundamentally flawed ([Krystal 2015](#); [National Institutes of Health 2005](#)). In approximately 15% of the patients with insomnia who have so-called primary insomnia, no associated condition exists to treat ([Edinger et al. 2011](#); [Ohayon 1997](#)). Evidence also indicates that treating the associated medical-psychiatric condition often fails to alleviate the insomnia and that insomnia has an adverse effect on the treatment response and course of depression, pain conditions, and anxiety disorders ([Krystal 2015](#); [Krystal et al. 2012](#); [National Institutes of Health 2005](#)). Further undermining the model that insomnia is invariably a symptom of psychiatric and medical conditions are the data referred to earlier indicating that insomnia is a risk factor for subsequent suicidality and psychiatric and medical conditions ([Avidan et al. 2005](#); [Baglioni](#)

et al. 2011; Bathgate et al. 2016; Breslau et al. 1996; Ford and Kamerow 1989; Harvey 2008; Johnson et al. 2000; Kessler et al. 2012; Koski et al. 1998; Stone et al. 2014; Vgontzas et al. 2013; Winsper and Tang 2014). These observations have led to a change in the paradigm for insomnia treatment.

It is now appreciated that the relation between insomnia and associated conditions is complex and often bidirectional and that directing treatment specifically to insomnia is generally warranted whether that insomnia occurs on its own or as a comorbid condition with psychiatric or medical conditions (National Institutes of Health 2005). Two primary types of treatment are available for specifically targeting insomnia disorder: 1) cognitive-behavioral therapy for insomnia (CBTI), the primary nonpharmacological therapy for insomnia, and 2) pharmacological therapy. A large evidence base supports the efficacy of CBTI for the treatment of insomnia, including primary insomnia and insomnia occurring with pain and major depressive disorder (Edinger et al. 2001, 2005; Manber et al. 2016; Morin et al. 2006; National Institutes of Health 2005). Pharmacotherapy, the focus of this chapter, is, by far, the most commonly administered treatment for insomnia disorder.

In this chapter, I review the neuropharmacology of pharmacological therapies for insomnia and examine their characteristics and clinical application. This information will optimize the medication management of insomnia.

---

## Sleep-Wake Pharmacology— Basis for Understanding Pharmacological Treatments for Insomnia

---

The pharmacological systems that regulate sleep-wake function consist of two types: 1) systems that promote sleep and 2) systems that promote wakefulness (Table 53-1) (Saper et al. 2005). These systems are mutually inhibitory such that greater activity in sleep-promoting systems inhibits the wake-promoting systems and vice versa, thereby stabilizing the state of an individual into either sleep or wake. The most important sleep-promoting systems include  $\gamma$ -aminobutyric acid (GABA), galanin, adenosine, and melatonin, whereas the wake-promoting systems include histamine, acetylcholine, norepinephrine, serotonin, and hypocretin/orexin (Saper et al. 2005). Agents that have therapeutic effects in treating insomnia either enhance the activity of one or more sleep-promoting systems or block the effects of one or more wake-promoting systems (Krystal et al. 2013b).

---

**TABLE 53-1. Sleep-wake neurotransmitters (sleep promoting and wake promoting)**

---

Key sleep-promoting systems	Key wake-promoting systems
$\gamma$ -Aminobutyric acid	Hypocretin/orexin
Galanin	Norepinephrine
Melatonin	Histamine
	Acetylcholine
	Serotonin
	Dopamine

---

Although there have long been agents available that differ in which of these systems they affect, it has generally been believed that the pharmacological mechanism of action of insomnia agents has no effect on their clinical effects (Krystal et al. 2013b). Clinical effects have been assumed to be determined by dose and pharmacokinetics (Krystal et al. 2013b). The higher the dosage, the greater the clinical sleep-enhancing effect; the higher the dosage and the more rapid the absorption, the sooner the clinical effect occurs; and the higher the dosage and the longer the elimination half-life, the longer the duration of sleep enhancement (Krystal et al. 2013b). This model emerged when the pharmacological management of insomnia was dominated by a group of agents—benzodiazepines (e.g., triazolam, temazepam, flurazepam) and nonbenzodiazepines (e.g., zolpidem, zaleplon, eszopiclone)—that had a common mechanism: sleep enhancement via positive allosteric modulation of GABA<sub>A</sub> receptors (Krystal 2009; Krystal et al. 2013b). Systematic data on clinical effects were essentially available only for these agents for which the pharmacokinetics/dose model is largely correct. Their peak effect occurs at the time of peak blood level, the speed of onset of clinical effects is proportional to rate of absorption, and the duration of effects is proportional to the elimination half-life. However, medications are available for the treatment of insomnia that have a fundamentally different mechanism and specifically block a single wake-promoting system (Krystal et al. 2013b). These agents with targeted, less global effects have the promise of an improved risk-benefit ratio when used in patients who have the type of sleep problem that is effectively treated with a particular agent. Studies characterizing the clinical effects of these medications have only relatively recently been carried out, and these studies verify the improved risk-benefit ratio and indicate that the model in which dose and pharmacokinetics are the prime drivers of clinical effects such that the mechanism of action is irrelevant to clinical effects is incorrect (Herring et al. 2016; Krystal et al. 2010, 2011; Michelson et al. 2014).

One agent that illustrates this point is doxepin 3–6 mg, a highly selective histamine H<sub>1</sub> receptor antagonist that enhances sleep by specifically blocking the wake-promoting effects of histamine (Krystal et al. 2010, 2011, 2013b). The peak therapeutic effect does not occur at peak blood level, which is approximately 3–4 hours after ingestion, but instead occurs at the end of the night about 4 hours later (Krystal et al. 2010, 2011, 2013b). According to the model in which pharmacokinetics and dose dominate clinical effects, this would not be possible and a drug with peak effect at the end of the night would be useless because it would cause prohibitive morning sedation or impairment (Krystal et al. 2013b). Because clinical effects should be proportional to blood level, and blood level only decreases incrementally over time, a drug with its biggest effect in hour 8 of an 8-hour night should have effects that are nearly as large in hour 9, the first hour of the day, at which time sleep-enhancing effects are problematic (Krystal et al. 2013b). Yet doxepin 3–6 mg has its greatest effects in hour 8 without clinically significant effects during waking 1 hour later (Krystal et al. 2010, 2011). This profile of effects is incompatible with a model in which therapeutic effects are dominated by pharmacokinetic factors and indicates that factors other than pharmacokinetics play an important role in determining clinical effects (Krystal et al. 2013b). These factors include the specific properties of the pharmacological system(s) modulated by a given drug and the activity in other systems that can affect sleep-wake function, which are determined by factors such as time of day and the behavior of the individual taking the medication and the psychosocial context (e.g., stress, novel environment, excitement) (Krystal et al. 2013b). The relevance of other systems was not apparent during the era when GABA<sub>A</sub>-positive allosteric modulators dominated insomnia pharmacotherapy, because those agents broadly

inhibit brain function, nonspecifically shutting down all of the wake-promoting systems. Agents that specifically inhibit a single wake-promoting system have brought to light how activity in systems that are not inhibited can contribute to clinical effects.

When using doxepin 3–6 mg as an example, the clinical effects of specifically blocking the histamine system reflect both the characteristics of the histamine system and the activity in parallel wake-promoting systems. Histamine is under control of the circadian clock, and its release varies systematically over the 24-hour cycle (Krystal et al. 2013b). When its release is minimal, the clinical effects of blocking histamine H<sub>1</sub> receptors should be minimal, whereas at times of significant release of histamine, a therapeutic effect can be expected. However, the activity of other sleep-wake-modulating systems that are not inhibited by doxepin 3–6 mg also plays a role. Whether blockade of histamine H<sub>1</sub> receptors manifests in a clinical sleep-enhancing effect will depend on the activity in other wake-promoting systems. If this activity is high, those systems will themselves sustain wakefulness even with significant blockade of H<sub>1</sub> receptors (Krystal et al. 2013b).

The activity in these parallel wake-promoting systems can be dependent on psychosocial context; for example, in an individual who is stressed or excited, noradrenergic neuronal activity is likely to be high and could maintain wakefulness despite histamine H<sub>1</sub> receptor antagonism (Krystal et al. 2013b). Another example of effects of time of day is that after an individual awakens for the day during the usual waking period, activity in the neuropeptide hypocretin/orexin system is increased and can maintain wakefulness even if H<sub>1</sub> receptors are blocked (Krystal et al. 2013b). This explains why doxepin 3–6 mg might have its largest effects in hour 8 of an 8-hour night and not have impairing effects after waking: at the end of the night, histamine release is high, and the parallel wake-promoting activity is normally relatively minimal, yet after waking, activity in parallel wake-promoting systems increases and can maintain wakefulness despite blockade of H<sub>1</sub> receptors (Krystal et al. 2013b). Thus, to determine the likely clinical effects of a medication, it is necessary to know not only dose and pharmacokinetic parameters but also mechanism of action in terms of which pharmacological system(s) it modulates, whether that system is modulated by the circadian rhythm and state (e.g., activity, stress, novelty), and what the circadian and state dependence are of the parallel pharmacological systems that could oppose or enhance clinical effects.

Accordingly, the model that is the basis for the current chapter is that “mechanism matters” and that three primary factors determine the clinical effects of medications used to treat insomnia: 1) mechanism of action, 2) drug pharmacokinetics, and 3) dosage. I review the characteristics of the various medications available for the treatment of insomnia organized by pharmacological mechanism of action. This includes reviews of the important sleep-promoting system-enhancing drugs, which consist of the benzodiazepines, nonbenzodiazepines, and melatonin receptor agonists, and the important wake-promoting system antagonists, which consist of the selective antihistamines, selective hypocretin/orexin receptor antagonists, selective adrenergic receptor antagonists, and nonselective wake-promoting system antagonists. It must be understood that in this chapter, the clinical effects of the agents with highly specific pharmacological effects can only be partially characterized because the activity in parallel systems that are not inhibited can vary greatly based on factors such as behavior and psychosocial context, as described earlier, making clinical effects more variable within and between individuals. As a result, rather than trying to characterize the full range of possible clinical effects as influenced by these factors for each agent, I indicate for each agent what the clinical effects are likely to be, assuming no contributions from behavioral

or psychosocial context factors, and then also indicate whether behavioral and psychosocial context factors could contribute to clinical effects.

## Pharmacological Treatments for Insomnia

---

### Agents That Improve Sleep by Enhancing Sleep-Promoting Systems

#### GABA<sub>A</sub>-Positive Allosteric Modulators

**Benzodiazepines.** The benzodiazepines are a group of medications that are GABA<sub>A</sub>-positive allosteric modulators and share a chemical structure (Krystal 2009; Minkel and Krystal 2013). The binding site on the GABA<sub>A</sub> receptor complex to which these agents bind is referred to as the *benzodiazepine binding site*. Through binding to this site, these agents broadly enhance GABA-mediated inhibition, which inhibits all of the wake-promoting systems and promotes sleep (Sieghart and Sperk 2002).

*Benzodiazepines used for the treatment of insomnia.* Five agents are indicated for the treatment of insomnia by the U.S. Food and Drug Administration (FDA): triazolam, flurazepam, temazepam, estazolam, and quazepam (Krystal 2009). Several other agents—clonazepam, alprazolam, and lorazepam—are commonly used to treat insomnia but have approved indications for conditions other than insomnia, such as anxiety and the treatment of seizures (Krystal 2009).

*Clinical therapeutic effects as indicated by available studies.* Triazolam, flurazepam, estazolam, quazepam, and temazepam have been found to have efficacy for the treatment of both sleep-onset problems and sleep-maintenance difficulty in at least one placebo-controlled trial (Krystal 2009).

*Effects on systems other than sleep-wake systems.* GABA is the predominant inhibitory neurotransmitter in the brain. For this reason, the benzodiazepines, which broadly enhance GABA<sub>A</sub>-mediated inhibition, can have very broad effects and affect many brain systems. Some of the associated effects can be therapeutic for some patients, including anxiety reduction, myorelaxant, and antiseizure effects (Krystal 2009). Other associated effects represent adverse effects, including cognitive impairment, motor impairment, and abuse potential (Krystal 2009).

*Optimal target patient population.* Benzodiazepines are best suited for use in those who can benefit from the effects these agents may have on systems other than sleep-wake systems, including those with anxiety or pain problems. These agents also have beneficial effects for sleep-onset problems that are stronger than other available options (Krystal 2009). However, the adverse effects of these medications outweigh the beneficial effects for most patients; for some with sleep-onset problems and comorbid conditions, these may have the best risk-benefit ratio of the available agents.

**Nonbenzodiazepines.** The term *nonbenzodiazepine* has been used to describe a set of agents that work by the same mechanism as the benzodiazepines, positive allosteric

modulation of GABA<sub>A</sub> receptors, but do not have the chemical structure of the benzodiazepines (Krystal 2009; Minkel and Krystal 2013).

*Nonbenzodiazepines used for the treatment of insomnia.* Three agents are indicated for the treatment of insomnia by the FDA: zolpidem, zaleplon, and eszopiclone (Krystal 2009). Zolpidem is also available in formulations other than an immediate-release formulation, including an extended-release version and a transoral version that is absorbed through the oral mucosa to a degree.

*Clinical therapeutic effects as indicated by available studies.* Zolpidem, zaleplon, and eszopiclone have been found to have efficacy for the treatment of sleep-onset problems in at least one placebo-controlled trial (Krystal 2009). However, only eszopiclone has been found to have therapeutic effects for sleep-maintenance problems (Krystal et al. 2003; Walsh et al. 2007). In addition, the extended-release formulation of zolpidem has been found to have beneficial effects on sleep maintenance (Krystal et al. 2008a), and both zaleplon and the transoral formulation of zolpidem have been found to have therapeutic effects for helping people return to sleep after middle-of-the-night awakenings (Roth et al. 2013; Zammit et al. 2006).

*Effects on systems other than sleep-wake systems.* Because the nonbenzodiazepines are GABA<sub>A</sub> allosteric modulators and GABA is widely distributed throughout the brain, like the benzodiazepines, the nonbenzodiazepines have the potential to have broad inhibitory effects on brain function. However, some evidence indicates that the clinical effects of nonbenzodiazepines are more limited than those of the benzodiazepines (Jia et al. 2009; Sanna et al. 2002). Benzodiazepines bind to four types of GABA<sub>A</sub> receptors that are believed to mediate the clinical effects of these agents, and evidence shows that the nonbenzodiazepines bind less broadly to these GABA<sub>A</sub> receptors, but the profile of binding differs among them (Jia et al. 2009; Sanna et al. 2002). Zolpidem and zaleplon bind relatively specifically to GABA<sub>A</sub> receptors, which are sleep promoting and also associated with cognitive and motor impairment, whereas eszopiclone tends to bind to GABA<sub>A</sub> receptors that are also associated with sleep enhancement and some degree of psychomotor impairment but relatively greater myorelaxant, anxiolytic, and possibly antidepressant effects. Clinical evidence for this is that unlike zolpidem, eszopiclone has been found to lead to improvement in anxiety, depression, and pain when combined with the usual therapy for these conditions in placebo-controlled trials (Fava et al. 2006, 2009, 2011; Goforth et al. 2014; Krystal et al. 2007b; Pollack et al. 2008).

*Optimal target patient population.* Nonbenzodiazepines are among the most widely administered insomnia therapies because of their strong effects on sleep onset and the perception that they have a better safety profile than the benzodiazepines. Generally, nonbenzodiazepines are the treatments of choice for pharmacotherapy of sleep-onset problems. Zolpidem (modified-release) and eszopiclone are also primary agents to consider for treating problems with sleep maintenance when they co-occur with sleep-onset problems; however, when sleep-maintenance problems occur without sleep-onset difficulty, other agents appear to have a more favorable risk-benefit profile (see “Selective Histamine H<sub>1</sub> Receptor Antagonists” section later in this chapter). The exception is for those individuals who have intermittent problems waking up in the middle of the night and are appropriate candidates for use of an as-needed rescue medication to help speed the return to sleep. In this case, transoral zolpidem and zaleplon are the treatments of choice

based on the available data ([Roth et al. 2013](#); [Zammit et al. 2006](#)). Finally, because only eszopiclone has been found to improve anxiety, depression, and pain outcomes when administered along with the usual first-line treatment for these conditions when they co-occur with insomnia, this medication should be considered as a first-line therapy for patients with insomnia occurring with these conditions ([Fava et al. 2006, 2009, 2011](#); [Goforth et al. 2014](#); [Krystal et al. 2007b](#); [Pollack et al. 2008](#)).

## Melatonin Receptor Agonists

Melatonin receptor agonists have melatonin receptor agonism as their primary clinical effect.

**Melatonin receptor agonists used for the treatment of insomnia.** Two selective melatonin receptor agonists are available: melatonin, available over the counter, and ramelteon, available by prescription only and FDA approved for the treatment of insomnia ([Krystal 2009](#)).

Melatonin is released by the pineal gland during the dark period of the circadian cycle ([Dubocovich et al. 2003](#)). Sleep enhancement is believed to occur via agonist effects at membrane-bound G protein-coupled melatonin type 1 (MT<sub>1</sub>) receptors, which inhibit the activity of neurons in the suprachiasmatic nucleus of the hypothalamus, the main circadian pacemaker ([Dubocovich et al. 2003](#)). Melatonin also binds to G protein-coupled MT<sub>2</sub> receptors, which are also located on suprachiasmatic nucleus neurons and induce shifts in the phase of the circadian rhythm ([Dubocovich et al. 2003](#)).

Ramelteon is a highly specific MT<sub>1</sub> and MT<sub>2</sub> agonist thought to have sleep-enhancing effects through its actions at the MT<sub>1</sub> receptor ([Krystal 2009](#)). It is substantially more potent than melatonin in affecting these receptors. It has an FDA indication for the treatment of insomnia only when the patient has problems with prolonged sleep onset.

*Clinical therapeutic effects as indicated by available studies.* A sizable set of studies that used a variety of dosages, formulations, and timing of dosing have been carried out to assess the effects of melatonin on individuals with sleep difficulty ([Buscemi et al. 2005](#); [Ferracioli-Oda et al. 2013](#)). These studies indicate that melatonin seems to be associated with improvement in sleep latency in insomnia patients with sleep-onset difficulties. Whether the degree of improvement associated with melatonin use is sufficient to be perceived as beneficial by many insomnia patients remains unclear ([Morin et al. 2015](#)). Furthermore, the optimal dose of melatonin for treatment of insomnia has yet to be established. Perhaps the most interest related to the use of melatonin to treat insomnia is in those with sleep difficulties co-occurring with autism or other neurodevelopmental disorders because reports indicate therapeutic effects ([Niederhofer et al. 2003](#); [Wirojanan et al. 2009](#)).

Ramelteon has been shown in several placebo-controlled trials to have therapeutic effects only on sleep-onset difficulties ([Krystal 2009](#)).

*Safety profile.* Melatonin has highly selective effects on melatonin receptors, and as a result, it has an excellent safety profile ([Wilson et al. 2010](#)). However, as mentioned earlier, the effects on MT<sub>2</sub> and melatonin type 3 (MT<sub>3</sub>) receptors can affect physiology, although by far the most important clinical effect mediated by MT<sub>2</sub> and MT<sub>3</sub> binding is MT<sub>2</sub>-mediated shifts in circadian rhythm ([Dubocovich et al. 2003](#)). This is believed to be responsible for the observation that melatonin is associated with greater therapeutic effects in those with

delayed sleep phase syndrome, in which the circadian sleep-wake cycle is shifted forward, than in insomnia patients (Buscemi et al. 2005; Ferracioli-Oda et al. 2013).

Like melatonin, ramelteon has an excellent safety profile as a result of having pharmacological effects that are limited to melatonin receptors (Krystal 2009). It does not have abuse potential and is safe in those with sleep apnea and chronic obstructive pulmonary disease (Kryger et al. 2007, 2009).

*Optimal target patient population.* The available data indicate that melatonin should be considered as first-line therapy for patients with insomnia occurring with autism and other neurodevelopmental problems as well as for those with insomnia occurring in the setting of circadian rhythm disorders (Buscemi et al. 2005; Ferracioli-Oda et al. 2013; Niederhofer et al. 2003; Wirojanan et al. 2009). Otherwise, melatonin can be considered for use in those with insomnia affecting only sleep onset.

Because ramelteon has effects only on sleep-onset difficulties, its use should be limited to those with only sleep-onset difficulties. It is especially well suited for use in those with obstructive sleep apnea and chronic obstructive pulmonary disease who have sleep-onset problems. It should also be considered for treating sleep-onset problems occurring in the setting of substance abuse or in individuals prone to substance abuse, but no studies have established its utility for this purpose.

## Agents That Improve Sleep by Blocking Wake-Promoting Systems

### Selective Histamine H<sub>1</sub> Receptor Antagonists

Selective H<sub>1</sub> receptor antagonists promote sleep by blocking the arousing effects of histamine through antagonism of the histamine H<sub>1</sub> receptor (Krystal et al. 2013b). The only highly selective histamine H<sub>1</sub> receptor antagonist is doxepin 3–6 mg. Doxepin was originally developed for treatment of depression and was FDA approved for treatment of depression and anxiety in dosages of 75–300 mg/day. In this dosage range, doxepin has clinically significant antagonism of several receptors, including adrenergic, serotonergic, and cholinergic receptors, and the serotonin and norepinephrine transporters in addition to H<sub>1</sub> receptor antagonism (Krystal et al. 2013b). However, because H<sub>1</sub> receptor antagonism is by far doxepin's most potent effect, at low enough dosages, this agent can have clinically significant effects only at H<sub>1</sub> receptors. The available evidence suggests that in the 3–6 mg range, doxepin is a highly selective H<sub>1</sub> receptor antagonist (Krystal et al. 2013b).

Available data from placebo-controlled trials carried out with doxepin 3 and 6 mg provided the first information about the clinical effects of selective wake-promoting system antagonism and, as discussed earlier, indicate that they differ from the clinical effects of the GABA<sub>A</sub> allosteric modulators (benzodiazepines and nonbenzodiazepines) (Krystal et al. 2013b). In addition to dose and pharmacokinetics, which essentially determine the clinical effects of those other agents, the clinical effects of doxepin are dependent on factors such as time of day and the state of the patient (e.g., activity, stress, novelty) (Krystal et al. 2010, 2011, 2013b). This dependence of clinical effects on factors other than dose and pharmacokinetics exists for all selective wake-promoting system antagonists and therefore represents a new paradigm for understanding the clinical effects of insomnia medications. As discussed earlier, the dependence of clinical effects of the selective antagonists on

factors other than dose and pharmacokinetics reflects that 1) the activity in the targeted wake-promoting systems is dependent on factors such as time of day and the state of the patient, and this will affect the degree of clinical effect occurring with antagonism; and 2) each wake-promoting system functions in parallel with other wake-promoting systems, which are not blocked by selective antagonism, and the activity in these systems is also affected by factors such as time of day and patient state (Krystal et al. 2013b). The reason this is not the case for the GABA<sub>A</sub> allosteric modulators is that they broadly inhibit all of the wake-promoting systems, and the clinical effects of enhancing GABA<sub>A</sub> activity are relatively less dependent on time of day and patient state factors (Krystal et al. 2013b).

### **Selective H<sub>1</sub> receptor antagonists used for the treatment of insomnia.**

Many medications that have histamine H<sub>1</sub> receptor antagonist effects are currently available and used to treat insomnia (Krystal et al. 2013b). However, the only highly selective H<sub>1</sub> receptor antagonist currently used in the treatment of insomnia is doxepin in 3- and 6-mg/day dosages. It is approved by the FDA for the treatment of insomnia with an indication only for treating problems staying asleep.

*Clinical therapeutic effects as indicated by available studies.* The clinical trials carried out with doxepin 3 and 6 mg indicate that this medication has consistent therapeutic effects on sleep maintenance, particularly in the last third of the night, without consistent therapeutic effects on sleep-onset problems (Krystal et al. 2010, 2011, 2013b). Notably, the largest effect size appears not at peak blood level (3–4 hours after dosing) but in the last hour of an 8-hour night. As discussed earlier, this could not occur with a GABA<sub>A</sub> allosteric modulator without prohibitive morning impairment. The fact that the largest effect occurs at a time other than at peak blood level and that morning impairment was not elevated over other medications that do not have significant effects in hour 8 is a clear indicator that clinical effects are dependent on factors beyond dose and pharmacokinetics (Krystal et al. 2010, 2011, 2013b). It is hypothesized that the reason the therapeutic effects are greatest at the end of the night is that the activity of histamine neurons is relatively high during this period, whereas the activity in the parallel wake-promoting systems is relatively low (Krystal et al. 2013b). However, after waking, the activity in the histamine system may increase further, and the activity in parallel wake-promoting systems increases, thereby sustaining normal waking function despite significant H<sub>1</sub> blockade (Krystal et al. 2013b).

*Effects on systems other than sleep-wake systems.* Given the relatively greater potency of doxepin for H<sub>1</sub> receptors over other receptors, it should be possible, in theory, to find a dosage for each individual that causes clinically significant H<sub>1</sub> receptor antagonist effects and no effects on any other pharmacological systems. The observed clinical effects indicate that the 3- and 6-mg/day dosages achieve this type of selectivity for many individuals (Krystal et al. 2010, 2011). However, for some individuals, these dosages may be above the range at which only histamine H<sub>1</sub> receptor antagonist effects are seen. When this is the case, the special advantages of highly selective antagonism are lost, and individuals may experience morning sedation and other adverse effects including anticholinergic (e.g., dry mouth, constipation, blurred vision) and antiadrenergic (e.g., orthostatic hypotension) symptoms.

*Optimal target patient population.* Because of the pharmacological selectivity of doxepin 3 and 6 mg, it can have an improved risk-benefit profile over other agents when

used to treat the type of problem that it specifically addresses: sleep-maintenance problems, particularly problems staying asleep at the end of the night (Krystal et al. 2013b). For this reason, doxepin 3–6 mg should be the treatment of choice for such individuals. Because of the absence of consistent therapeutic effects for sleep-onset problems, this medication should be reserved for those individuals with difficulties staying asleep, particularly toward the end of the night, who do not have problems falling asleep. The lack of abuse potential suggests that this medication might be particularly useful in abuse-prone individuals with sleep-maintenance problems. The fact that H<sub>1</sub> receptor antagonism is the key mechanism of anti-allergy effects also suggests that this medication should be among the treatments of choice for sleep difficulties occurring with significant allergy symptoms.

### Selective Hypocretin/Orexin Receptor Antagonists

Hypocretin and orexin are the peptides released by neurons located in the lateral hypothalamus that are among the most important factors maintaining wakefulness (Krystal et al. 2013a; Sakurai 2014). The wake-promoting effects of these peptides are mediated by their binding to two receptors referred to as OX<sub>1</sub> and OX<sub>2</sub> (Sakurai 2014). Selective hypocretin/orexin receptor antagonists enhance sleep by blocking OX<sub>1</sub> receptors, OX<sub>2</sub> receptors, or both. The tremendous specificity of this effect is illustrated by the fact that there are only 10,000–20,000 hypocretin/orexin-releasing neurons in the entire brain (Sakurai 2014). This specificity provides the potential for drugs that block OX<sub>1</sub> and OX<sub>2</sub> receptors to promote sleep while having minimal effects on other brain functions. Because hypocretin/orexin neurons do modulate activity in many brain areas, these agents would be expected to have some effects on functions other than sleep. However, the relative lack of effect on areas of the brain mediating cognitive and motor function suggests that these agents have the potential to be without many of the adverse effects that have been associated with agents predominantly used to treat insomnia such as the benzodiazepines and nonbenzodiazepine GABA<sub>A</sub> allosteric modulators.

**Selective hypocretin/orexin receptor antagonists used for the treatment of insomnia.** The only available hypocretin/orexin receptor antagonist currently available for clinical use is suvorexant, which is a dual (OX<sub>1</sub> and OX<sub>2</sub>) receptor antagonist (Herring et al. 2016; Michelson et al. 2014). The FDA granted it approval for the treatment of insomnia with indicators for treating sleep-onset and sleep-maintenance difficulties.

*Clinical therapeutic effects as indicated by available studies.* The clinical effects of suvorexant have been documented in several large-scale placebo-controlled trials (Herring et al. 2016; Michelson et al. 2014). Two were in primary insomnia patients, and one included patients with comorbid conditions, but these individuals were not included in large enough numbers to allow subgroup analysis. These studies indicate that this medication has therapeutic effects on sleep onset and sleep maintenance, consistent with its FDA indications.

*Effects on systems other than sleep-wake systems.* Suvorexant has minimal effects on systems other than the hypocretin/orexin system. As a result, the primary adverse effects of these agents are relatively limited and due to decreased hypocretin/orexin-mediated function. The primary such effect is daytime sedation or fatigue, but cough, dry

mouth, abnormal dreams, and headache also occur with this medication ([Herring et al. 2016](#); [Michelson et al. 2014](#)).

*Optimal target patient population.* Hypocretin/orexin receptor antagonists are among the agents that could be considered for first-line use in patients with problems both falling and staying asleep. An additional target population is insomnia patients with mild to moderate chronic obstructive pulmonary disease or obstructive sleep apnea because of evidence that these drugs do not exacerbate these conditions ([Sun et al. 2015, 2016](#)). The amygdala, lateral septum, periaqueductal gray, and parabrachial nucleus have important projections to hypocretin/orexin neurons, which are believed to mediate stress- or anxiety-associated increases in arousal; thus, hypocretin/orexin receptor antagonists should, in theory, be particularly useful for patients with sleep problems occurring in the setting of stress or anxiety ([Krystal et al. 2013a](#); [Scammell and Winrow 2011](#)). Hypocretin/orexin receptor antagonists also would be expected to be particularly helpful for those trying to sleep at a time of day that is not their circadian sleep period, because evidence showed that activity in the hypocretin/orexin neurons is driven by the circadian clock and is a prime factor allowing the maintenance of wakefulness during the usual circadian wake period ([Krystal et al. 2013a](#)). Similarly, individuals who tend to get energized in the late evening and have difficulty shutting down to sleep also would likely be helped by selective hypocretin/orexin receptor antagonists. However, studies are needed to determine whether these theoretical optimal target patient populations are actually best treated with hypocretin/orexin receptor antagonists.

### Selective $\alpha_1$ -Adrenergic Receptor Antagonists

Medications that are selective  $\alpha_1$ -adrenergic receptor antagonists have long been available by prescription for the treatment of hypertension and benign prostatic hypertrophy. These agents include prazosin, silodosin, doxazosin, tamsulosin, alfuzosin, and terazosin. These agents may have sleep-enhancing effects by blocking the wake-promoting effects of norepinephrine, one of the important wake-promoting systems ([Krystal and Davidson 2007](#); [Krystal et al. 2013b](#); [Saper et al. 2005](#)). These drugs do so by blocking  $\alpha_1$ -adrenergic receptors, which are primarily excitatory postsynaptic receptors. These agents have long been of interest for modulating anxiety. Evidence that central noradrenergic hyperactivity plays an important role in mediating anxiety has existed for more than 40 years ([Charney and Redmond 1983](#)). A sizable literature indicates that agents that dampen central noradrenergic neuronal activity or blunt noradrenergic system-mediated activation, such as  $\alpha_1$ -adrenergic receptor antagonists, have clinical anxiolytic effects. Within this context, selective  $\alpha_1$ -adrenergic receptor antagonists have found application in the treatment of sleep difficulties.

A series of relatively recent studies documented the therapeutic effects of prazosin, a selective  $\alpha_1$ -adrenergic receptor antagonist, on sleep difficulties in patients with posttraumatic stress disorder (PTSD) ([Goddard et al. 2010](#); [Raskind et al. 2003, 2007, 2013](#); [Taylor et al. 2008](#)). Because of the selectivity of this agent for  $\alpha_1$  receptors, these agents have the potential to improve sleep difficulties in patients with anxiety-related difficulties in a specific, targeted way. They would be expected to have minimal effects on brain function in areas not significantly activated by noradrenergic neurons, including areas related to reward, cognition, and motor function, and, like the selective hypocretin/orexin receptor antagonists and selective  $H_1$  receptor antagonists, have the potential to improve sleep difficulties without many of the adverse effects that have limited the use of benzodiazepines and nonbenzodiazepines. As with the other selective agents,

the potential for adverse daytime sedating effects is also limited by the other parallel wake-promoting systems that are not inhibited by  $\alpha_1$ -adrenergic receptor antagonism, which can maintain wakefulness even though adrenergic-mediated arousal is blunted. As a result, selective  $\alpha_1$ -adrenergic receptor antagonists can specifically improve adrenergic-mediated arousal, primarily driven by stress or anxiety and novelty, in a highly targeted way, thereby minimizing associated adverse effects.

**Selective  $\alpha_1$ -adrenergic receptor antagonists used for the treatment of insomnia.** Although several selective  $\alpha_1$ -adrenergic receptor antagonists are available, the only one that has been significantly studied and used to any significant extent for treating sleep problems is prazosin (Goddard et al. 2010; Krystal and Davidson 2007; Raskind et al. 2003, 2007, 2013; Taylor et al. 2008). However, no selective  $\alpha_1$ -adrenergic receptor antagonists have an FDA indication for treating insomnia.

*Clinical therapeutic effects as indicated by available studies.* The available studies suggest that prazosin consistently improves sleep-maintenance difficulties and nightmares in patients with PTSD (Goddard et al. 2010; Krystal and Davidson 2007; Raskind et al. 2003, 2007, 2013; Taylor et al. 2008). Studies of the effects of this agent on primary insomnia or insomnia occurring with conditions other than PTSD have not been carried out.

*Effects on systems other than sleep-wake systems.* Prazosin has minimal effects on systems other than the noradrenergic. As a result, the primary adverse effects of this agent is relatively limited and due to decreased noradrenergic-mediated function. The primary such effect is orthostatic hypotension and associated dizziness (Goddard et al. 2010; Raskind et al. 2003, 2007, 2013; Taylor et al. 2008). Dry mouth, sweating, nasal congestion, and sedation also have been reported to occur.

*Optimal target patient population.* Prazosin is currently the treatment of choice for patients with sleep difficulties occurring in the setting of PTSD. Although studies are lacking, the use of this agent in treating sleep problems in patients with other anxiety disorders is of high interest. It also should be noted that prazosin is the only medication shown to have a strong effect on nightmares in any context. Nightmares are common in PTSD patients but also occur in those without PTSD, and no established therapies are available to use in this case. As a result, when faced with the need to treat nightmares in a patient who does not have PTSD, it would be reasonable to consider a trial of prazosin.

### **Nonselective Wake-Promoting System Antagonists**

Some agents that were originally developed for the treatment of allergies are generally referred to as *antihistamines*, because they all have significant histamine  $H_1$  receptor antagonism. However, none of these agents are particularly potent or selective  $H_1$  receptor antagonists, and all have clinically significant effects on pharmacological systems other than the histamine system (Krystal et al. 2013b). Notably, agents such as doxepin and mirtazapine are more potent and selective histamine  $H_1$  receptor antagonists than any of these antihistamines, but they were never referred to by this name because they were originally developed for the treatment of depression and not allergy. As a result, they are generally referred to as *antidepressants*. Thus, it is important to appreciate that the term *antihistamine* is more a reflection of the original targeted disorder than it is an indicator of drug pharmacology. A more appropriate term for these agents would be

*nonselective antihistamines.* The nonselective antihistamines primarily used for the treatment of insomnia are agents that are available over the counter. They all have significant muscarinic cholinergic receptor antagonism in addition to H<sub>1</sub> receptor antagonism, and some have other important pharmacological effects (Krystal et al. 2013b). There is reason to believe that these nonhistaminergic effects influence both clinical effects on sleep problems and the side-effect profile (Krystal et al. 2013b). These agents promote sleep primarily by blocking the arousing effects of both histamine and acetylcholine.

**Nonselective antihistamines used for the treatment of insomnia.** Two nonselective antihistamines are the predominant members of this group of medications used for insomnia treatment: diphenhydramine and doxylamine (Krystal et al. 2013b). Both are active ingredients in many over-the-counter sleep treatments.

*Clinical therapeutic effects as indicated by available studies.* Remarkably little systematic research has been carried out on the sleep effects of the nonselective antihistamines considering how frequently these agents are used to treat sleep difficulties. Only two placebo-controlled trials have been completed (Glass et al. 2008; Morin et al. 2005). One was a crossover study including 20 older adults with primary insomnia indicating that diphenhydramine 50 mg decreased number of awakenings compared with placebo but had no other significant effects on sleep problems (Glass et al. 2008). The other study evaluated diphenhydramine 25 mg in a parallel-group trial in approximately 120 adults with relatively mild insomnia (Morin et al. 2005). In this study, diphenhydramine led to significant improvement in self-reported sleep efficiency (time asleep/time in bed) but not in polysomnographic sleep efficiency or self-reported or polysomnographic sleep-onset latency or total sleep time.

*Effects on systems other than sleep-wake systems.* The adverse effects of the nonselective antihistamines include, in addition to daytime sedation, side effects primarily reflecting cholinergic receptor antagonism such as dry mouth, dizziness, constipation, and blurred vision (Glass et al. 2008; Krystal et al. 2013b; Morin et al. 2005). The cholinergic receptor antagonism also increases the risk for urinary retention, memory impairment, and delirium, particularly in older individuals.

*Optimal target patient population.* The limited available data do not make a strong case for the utility of the nonselective antihistamines. However, to the extent that they have therapeutic effects, they appear to be limited to improvements in sleep maintenance and not sleep onset (Glass et al. 2008; Morin et al. 2005). Thus, use should be limited to those without sleep-onset difficulty who have problems with sleep maintenance. The H<sub>1</sub> and cholinergic receptor antagonism of the agents suggests that they would be best suited for use in individuals experiencing sleep problems related to allergies or those with nasal congestion due to other causes such as upper respiratory infection.

## **Antidepressants**

The group of agents developed for the treatment of depression are referred to as *antidepressants*. They have broad pharmacological effects, being antagonists at several receptors, including at least one wake-promoting system, which leads these medications to have sleep-promoting effects (Krystal 2010). These medications are used off label for the treatment of insomnia, often at dosages lower than the antidepressant dosage. With a few exceptions, the risk-benefit profile of these medications for the treatment of insomnia has

not been evaluated in placebo-controlled trials. This is a significant limitation to including them in an evidence-based approach to insomnia therapy. However, it can be assumed that their nonspecific pharmacology leads them to have therapeutic effects on conditions other than insomnia, some of which are common comorbid conditions such as depression, anxiety, and pain, but at the same time associates these medications with a relatively high side-effect burden (Krystal et al. 2013b).

**Antidepressants used for the treatment of insomnia.** The antidepressants most commonly used to treat insomnia include amitriptyline, doxepin, trimipramine, trazodone, and mirtazapine (Krystal 2010). Amitriptyline, doxepin (25–50 mg), and trimipramine promote sleep primarily through antagonism of norepinephrine, histamine, and acetylcholine receptors, whereas trazodone promotes sleep primarily through antagonism of norepinephrine, histamine, and serotonin type 2 (5-HT<sub>2</sub>) receptors, and mirtazapine promotes sleep primarily through antagonism of histamine and 5-HT<sub>2</sub> receptors.

*Clinical therapeutic effects as indicated by available studies.* Of the antidepressants used to treat insomnia, double-blind, placebo-controlled studies of insomnia treatment have been carried out only with trimipramine, doxepin (25–50 mg), and trazodone (Krystal 2010). Trimipramine has been studied in primary insomnia patients at dosages from 50 to 200 mg and was found to improve self-reported sleep quality and sleep efficiency (total sleep time/time in bed) but not sleep-onset latency (Hohagen et al. 1994; Riemann et al. 2002). Studies carried out in insomnia patients with doxepin 25–50 mg indicate that, unlike doxepin 3–6 mg, therapeutic effects on sleep onset, sleep maintenance, and sleep quality were seen (Hajak et al. 1996, 2001; Rodenbeck et al. 2003). Trazodone has been found to have therapeutic effects on sleep when used as adjunctive treatment to antidepressant medications in depressed patients with insomnia (Kaynak et al. 2004; Nierenberg et al. 1994). Trazodone (50 mg) also was evaluated in a placebo-controlled trial in primary insomnia patients, and although improvement was reported in some sleep indices in the first week of treatment, no significant effects compared with placebo were found in the second week of this 2-week study (Walsh et al. 1998). A pilot trial of trazodone as a treatment for insomnia in abstinent alcoholic individuals suggested therapeutic effects on sleep-maintenance problems (Le Bon et al. 2003).

*Effects on systems other than sleep-wake systems.* All of the antidepressants with sleep-enhancing effects have effects on pharmacological systems other than those related to enhancing sleep. Some of these effects can be assets to therapy because they include therapeutic effects on conditions that often co-occur with sleep disturbance, including depression, anxiety, and pain (Krystal 2010; Krystal et al. 2013b). However, some non-sleep-related effects may lead to adverse effects. The specific adverse effects seen depend on both mechanism of action and dose. The higher the dose, the greater the effects on more pharmacological systems, including those mediating side effects. Those agents with significant muscarinic receptor antagonism are associated with a risk of dry mouth, constipation, blurred vision, urinary retention, dizziness, memory impairment, and delirium (Krystal 2010; Krystal et al. 2013b) (Table 53–2). Those with significant adrenergic receptor antagonism are associated with a risk of orthostatic hypotension and dizziness (see Table 53–2). Weight gain, although incompletely understood, appears to be particularly likely with agents with histamine, 5-HT<sub>2C</sub>, and acetylcholine receptor antagonism.

**TABLE 53-2. Properties of agents commonly used to treat insomnia**

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target aspect
<b>Benzodiazepines</b>						
Triazolam	GABA	—	Insomnia	0.125–0.8	2–5.5	Onset, maintenance
Temazepam	GABA	—	Insomnia	7.5–30	8–20	Onset, maintenance
Flurazepam	GABA	—	Insomnia	15–30	40–250	Onset, maintenance
Lorazepam	GABA	—	Anxiety	0.125–1	12–15	Non-maintenance
Clonazepam	GABA	—	Anxiety, seizures	0.25–2	35–40	Non-maintenance
Alprazolam	GABA	—	Anxiety	1–3	12–14	Non-maintenance
<b>Nonbenzodiazepines</b>						
Zolpidem	GABA	—	Insomnia: sleep onset	5–10	2.0–5.5	Onset

*Note.* 5-HT=serotonin; Ach=acetylcholine; COPD=chronic obstructive pulmonary disease; GABA=γ-aminobutyric acid; HA=histamine; N/A=not applicable; NE=norepinephrine; PTSD=posttraumatic stress disorder.

<sup>a</sup>At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or both.

Agent	Enhancement of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target aspect
Zolpidem extended release	GABA	—	Insomnia: sleep onset; sleep maintenance in first 6 hours of the night	6.25–12.5	2.0–5.5	Onset of sleep
Transoral zolpidem	GABA	—	Insomnia: middle of the night	1.75–3.5	2.0–5.5	Middle of the night
Zaleplon	GABA	—	Insomnia: middle of the night	10–20	0.9–1.1	Onset of sleep
Eszopiclone	GABA	—	Insomnia: sleep onset and sleep maintenance	1–3	6–7	Onset of sleep

#### Selective melatonin receptor agonists

Melatonin	Melatonin	—	N/A (available over the counter as herbal supplement)	0.3–10	0.6–1	Onset of sleep
Ramelteon	Melatonin	—	Insomnia: sleep onset	8	0.8–2	Onset of sleep

#### Selective histamine H<sub>1</sub> receptor antagonists

*Note.* 5-HT=serotonin; Ach=acetylcholine; COPD=chronic obstructive pulmonary disease; GABA=γ-aminobutyric acid; HA=histamine; N/A=not applicable; NE=norepinephrine; PTSL

<sup>a</sup>At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance

Agent	Enhance- ment of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target aspects
Doxepin	—	HA	Insomnia: sleep maintenance	3–6	10–50	Main

#### Selective hypocretin/orexin receptor antagonists

Suvorexant	—	Hypocretin/orexin	Insomnia: sleep onset and maintenance	10–20	9–13	Onset main
------------	---	-------------------	--	-------	------	---------------

#### $\alpha_1$ -Adrenergic receptor antagonists

Prazosin	—	NE	Hypertension	2–15	2–3	Main in pa
----------	---	----	--------------	------	-----	------------------

#### Nonspecific wake-promoting system antagonists

Diphenhydramine	—	HA, Ach	Over-the-counter sleep and allergy medication	25–50	5–11	Main
-----------------	---	---------	--	-------	------	------

*Note.* 5-HT=serotonin; Ach=acetylcholine; COPD=chronic obstructive pulmonary disease; GABA= $\gamma$ -aminobutyric acid; HA=histamine; N/A=not applicable; NE=norepinephrine; PTSD=

<sup>a</sup>At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance

<b>Agent</b>	<b>Enhance- ment of</b>	<b>Blockade of</b>	<b>FDA indication</b>	<b>Usual dosage (mg)</b>	<b>Elimination half-life (hours)</b>	<b>Target aspects</b>
Doxylamine	—	HA, Ach	Over-the-counter sleep and allergy medication	25-50	10-12	Non
Amitriptyline	—	NE, HA, Ach	Depression	10-100	10-100	Non
Doxepin	—	NE, HA, Ach	Depression	25-75	10-50	Ons m
Trimipramine	—	NE, HA, Ach	Depression	25-100	15-40	Main

<sup>a</sup>At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance

Agent	Enhance- ment of	Blockade of	FDA indication	Usual dosage (mg)	Elimination half-life (hours)	Target aspiration
Trazodone	—	5-HT <sub>2</sub> , NE, HA	Depression	25– 150	7–15	Non
Mirtazapine	—	5-HT <sub>2</sub> , HA	Depression	7.5–30	20–40	Non
Olanzapine	—	HA, NE, Ach, 5-HT <sub>2</sub> , DA	Psychosis	2.5–20	20–54	Non
Quetiapine	—	HA, NE, Ach, 5-HT <sub>2</sub> , DA	Psychosis	25– 200	7	Non

*Note.* 5-HT=serotonin; Ach=acetylcholine; COPD=chronic obstructive pulmonary disease; GABA=γ-aminobutyric acid; HA=histamine; N/A=not applicable; NE=norepinephrine; PTSD=posttraumatic stress disorder.

<sup>a</sup>At least one placebo-controlled trial reporting efficacy for either sleep-onset, sleep-maintenance, or total sleep time.

**Optimal target patient population.** Antidepressants with sleep-enhancing effects are best suited for use in patients with sleep problems occurring in conjunction with a condition that they effectively treat. These conditions vary depending on the medication but may include depression, anxiety, or pain (see [Table 53-2](#)) ([Krystal 2010](#)). Two main approaches are used for treating insomnia occurring comorbidly with another such condition. One is to administer single-agent therapy with one of these antidepressants. The other is to combine a sleep-targeted drug with a treatment aimed at improving the

associated condition. No data indicate which approach is preferred. However, an advantage of the two-treatment approach is that it allows a wider range of treatments for the associated conditions, including nonsedating interventions. For example, in a depressed patient with insomnia disorder, one could combine bupropion as an antidepressant with a sleep-targeted intervention, whereas bupropion alone lacks sleep-enhancing effects and thus could not reasonably be used as a single-agent therapy (Krystal et al. 2007b). Antidepressants also can be considered for use in treatment-resistant insomnia because of their broad pharmacological effects.

## Antipsychotics

The antipsychotics share similarities to the antidepressants in being medications with broad pharmacological effects that were developed for an indication other than insomnia disorder but are used off label in treating insomnia at lower-than-usual dosages. In this case, they were developed for treatment of psychosis, although some have more recently received FDA indications for bipolar mania and depression as well. Like the antidepressants, the antipsychotics are antagonists at several receptors, at least one of which includes a wake-promoting system, which is the basis for their sleep-promoting effects (Krystal 2010; Krystal et al. 2008b). Very limited data are available on the risk-benefit profile of these medications for the treatment of insomnia. In fact, even fewer placebo-controlled trials have been carried out with antipsychotics than with antidepressants, which is a significant limitation to including the antipsychotics in an evidence-based approach to insomnia therapy. However, it can be assumed that their nonspecific pharmacology leads them to have therapeutic effects on conditions other than insomnia, some of which are common comorbid conditions such as schizophrenia, mania, delirium, depression, anxiety, and pain, but at the same time associates these medications with a relatively high side-effect burden (Krystal 2010; Krystal et al. 2008b, 2013b).

**Antipsychotics used for the treatment of insomnia.** The antipsychotics most commonly used to treat insomnia include olanzapine and quetiapine (Krystal 2010; Krystal et al. 2008b). Both of these agents promote sleep primarily through antagonism of histamine, norepinephrine, acetylcholine, 5-HT<sub>2</sub>, and dopamine receptors (Krystal 2010; Krystal et al. 2008a).

*Clinical therapeutic effects as indicated by available studies.* No large-scale systematic studies of the use of any of these agents in the treatment of insomnia have been done. Several small studies have been carried out in healthy control subjects and patients with schizophrenia and mood disorders, which included polysomnographic endpoints that provided a preliminary indication that olanzapine improves both sleep-onset and sleep-maintenance problems (Krystal 2010). An open-label trial of quetiapine 25–75 mg in primary insomnia patients provided preliminary evidence that this agent improves sleep-onset latency and total sleep time (Krystal 2010). A double-blind, placebo-controlled, randomized trial of quetiapine 25 mg was carried out in insomnia patients but did not find any significant effects of drug compared with placebo (Tassniyom et al. 2010).

*Effects on systems other than sleep-wake systems.* All of the antipsychotics with sleep-enhancing effects have effects on pharmacological systems other than those related to enhancing sleep. Some of these effects can be assets to therapy because they include therapeutic effects on conditions that often co-occur with sleep disturbance, including schizophrenia, mania, depression, anxiety, and pain (Krystal 2010; Krystal et al. 2008b). However, some non-sleep-related effects may lead to adverse effects. Like with the

antidepressants, the specific adverse effects seen with the antipsychotics depend on both mechanism of action and dose. The higher the dose, the greater the effects on more pharmacological systems, including those mediating side effects (see [Table 53-2](#)). Those agents with significant dopamine receptor antagonism are associated with a risk of parkinsonian side effects, acute dystonic reactions, and tardive dyskinesia ([Krystal et al. 2008b](#)). Those with muscarinic cholinergic receptor antagonism are associated with a risk of dry mouth, constipation, blurred vision, urinary retention, dizziness, memory impairment, and delirium ([Krystal 2010](#); [Krystal et al. 2013b](#)). Those with significant adrenergic receptor antagonism are associated with a risk of orthostatic hypotension and dizziness. Weight gain, although incompletely understood, appears to be particularly likely with agents with histamine, 5-HT<sub>2</sub>, and acetylcholine receptor antagonism.

*Optimal target patient population.* Antipsychotics with sleep-enhancing effects are best suited for use in patients with sleep problems occurring in conjunction with a condition that they effectively treat. These conditions vary depending on the medication but may include schizophrenia, mania, delirium, depression, anxiety, or pain (see [Table 53-2](#)) ([Krystal 2010](#); [Krystal et al. 2008a](#)). Antipsychotics also can be considered for use in treatment-resistant insomnia patients because of their broad pharmacological effects, but the cost of this relatively broad pharmacological effect is a relatively unfavorable side-effect profile that must be taken into account when deciding whether to administer these agents.

---

## Conclusion

---

An increasing set of medications is becoming available to help patients with insomnia. For many years, investigators believed that the mechanism of action of insomnia medications was without clinical implications. Clinical effects were assumed to be determined primarily by dose and drug pharmacokinetic properties. It is now clear that this is not the case. Mechanism of action matters. Clinical effects reflect not only dose and pharmacokinetics but also the specific properties of the pharmacological system(s) being modulated by a given drug and the nature and state of other parallel pharmacological systems that continue to function during the period of action of that drug. As a result, factors such as time of day, the behavior of the patient, and the patient's psychosocial context (e.g., stress, novelty, excitement) can play a role in determining the clinical effects of medications used to treat insomnia. This has become apparent only through experience with the relatively more recently available agents, including selective antagonists of a single wake-promoting system. These agents promise improved risk-benefit ratio over older, broadly acting agents for specific subgroups of patients who have the specific type of sleep problem targeted by a given selective wake-promoting system antagonist. To take advantage of this promise requires knowledge of the specific clinical effects of each agent and the type of sleep difficulty that they best treat. It is also important to appreciate the instances when it is best to use a nonselective, more broadly acting agent. Knowledge of the properties of each agent and the best target patient subpopulation can then serve as a basis for optimally matching patients to therapies in clinical practice. I hope this chapter provided the scientific basis and practical information needed to work toward achieving this type of personalization of insomnia therapies and ultimately to achieving better clinical outcomes in insomnia patients.

## CHAPTER 54

# Treatment of Chronic Pain

Kurt Kroenke, M.D.

Pain is the most common symptom reported in both the general population and the general medical setting (Kroenke 2003b; Sternbach 1986; Verhaak et al. 1998). Pain complaints account for more than 40% of all symptom-related outpatient visits, or over 100 million ambulatory encounters in the United States alone each year (Schappert 1992). Among the 30 diseases producing the most disability in the United States, pain conditions account for the 1st (low back pain), 4th (neck pain), 5th (other musculoskeletal disorders), 9th (osteoarthritis), and 14th (migraine headache) leading causes (Murray et al. 2013). The total costs (health care, lost productivity, and other costs) attributable to pain in the United States is more than \$600 billion annually, a figure that exceeds the annual costs of heart disease (\$309 billion), cancer (\$243 billion), and diabetes (\$188 billion) (Henschke et al. 2015). In 2008, analgesics constituted 10.1% of all drugs prescribed for adults (ranking a close second to antidepressants, at 10.8%) (Institute of Medicine 2011). Yet nonopioid analgesics fail to provide adequate relief for many patients (Curatolo and Bogduk 2001; Nuckols et al. 2014), and physicians' concerns about regulatory restrictions and risks of tolerance or addiction constrain the prescribing of opioid analgesics for noncancer pain (Joranson et al. 2002). Moreover, opioids themselves may provide only moderate reductions in chronic pain (Furlan et al. 2006; Martell et al. 2007) and may fail to improve (or may even worsen) psychological outcomes (e.g., depression) or functional status even when they do alleviate the pain (Moulin et al. 1996). At the same time, clinicians are being pressured to respond to pain as the "fifth vital sign" (Joint Commission on Accreditation of Healthcare Organizations 2000). In House Resolution 1863, the National Pain Care Policy Act of 2003, Congress declared the period 2001–2010 the "Decade of Pain Control and Research." Indeed, persistent pain is a major international health problem (Gureje et al. 1998), prompting the World Health Organization to endorse a global campaign against pain (Breivik 2002). Persistent pain may lead to excessive surgery or other expensive or invasive procedures and is the leading reason for use of complementary and alternative medicine (CAM) (Astin 1998).

---

## Psychiatric Comorbidity

---

Pain is even more prevalent in patients with psychiatric comorbidity, particularly mood disorders. The overlap between pain and depression ranges from 30% to 60% (Ang et al. 2006; Bair et al. 2003; Magni et al. 1993). Pain is a strong predictor of both the onset and

the persistence of depression ([Ohayon and Schatzberg 2003](#)), and depression is likewise a powerful predictor of pain, particularly persistent pain ([Bair et al. 2003](#); [Gureje et al. 1998](#)). Concurrent pain and depression have a much greater impact than either disorder alone on multiple domains of functional status as well as health care utilization ([Bair et al. 2003](#)). Comorbid depression worsens disability and decreases active coping in patients suffering from pain ([Arnow et al. 2006](#); [Demyttenaere et al. 2006](#)). Comorbidity decreases the likelihood of a favorable response of either condition to treatment and also diminishes patient satisfaction with treatment ([Bair et al. 2004](#); [DeVeauugh-Geiss et al. 2010](#); [Karp et al. 2005](#); [Kroenke et al. 2008](#); [Mavandadi et al. 2007](#); [Thielke et al. 2007](#)). Thus, reliable methods for assessing the presence and severity of pain in patients with depression (particularly those not responding to initial treatment) and strategies for effectively and efficiently integrating evidence-based depression care into the management of patients with chronic pain are sorely needed ([Kroenke 2003a](#)).

Although not as extensively studied, the comorbidity of pain with anxiety appears to be nearly as strong as its comorbidity with depression ([Bair et al. 2008, 2013](#); [Kroenke 2003b](#); [Kroenke and Price 1993](#); [Kroenke et al. 1994, 1997](#); [McWilliams et al. 2003](#)). Indeed, a global study conducted by the World Health Organization in 17 countries and involving more than 85,000 community-dwelling adults showed that pain is associated with mood and anxiety disorders, but not with alcohol use disorders ([Gureje et al. 2008](#)). The prevalence of specific mood and anxiety disorders was lowest among persons with no pain, intermediate among those with one pain site, and highest among those with multiple pain sites. Relative to persons not reporting pain, the age-sex adjusted odds ratios were 1.8 (95% confidence interval [CI]=1.7-2.0) for mood disorders and 1.9 (95% CI=1.8-2.1) for anxiety disorders for persons with single-site pain, and 3.7 (95% CI=3.3-4.1) for mood disorders and 3.6 (95% CI=3.3-4.0) for anxiety disorders among those with multisite pain.

---

## Definition and Classification of Pain

---

The [International Association for the Study of Pain \(2012\)](#) defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” Although there are more complex approaches to classifying pain, a pragmatic and frequently used system broadly classifies pain as either *nociceptive* or *neuropathic* ([Basbaum et al. 2005](#)). Nociceptive pain includes most cases of acute pain in which a strong, noxious stimulus impacts the skin or deep tissue. Acute pain resolves after the noxious stimulus has been removed, but inflammatory and other mechanisms may lead to persistence of nociceptive pain for weeks, months, or years (i.e., chronic pain). Many pain conditions, including arthritis and other musculoskeletal disorders, migraine and tension headache, and chronic widespread pain conditions such as fibromyalgia, would be classified under the broad rubric of nociceptive pain.

A second type of chronic pain, neuropathic pain, arises from injury to the peripheral or central nervous system. Examples include postherpetic neuralgia, painful diabetic neuropathy, phantom limb pain, and sciatica. Neuropathic pain is often characterized as burning, paroxysmal, stabbing, buzzing, or electric shock-like. Some conditions, such as low back pain, may include both nociceptive components (arising from the muscles or contiguous tissues) and neuropathic components (radicular pain or sciatica).

Persons with chronic pain often suffer from spontaneous ongoing pain. Also, stimuli that are normally not painful (movement, light touch) become painful, a phenomenon known as *allodynia*. Examples include pain produced by touching sunburned skin or moving an

arthritic joint. *Hyperalgesia* is exacerbated pain produced by a stimulus that is expected to be only mildly painful (e.g., slapping sunburned skin). These phenomena may be related to central sensitization, which has been proposed as a common mechanism underlying unexplained pain syndromes such as fibromyalgia.

Sometimes the broader category of nociceptive pain is subclassified into *somatic* pain (triggered in the skin, muscles, joints, or fascia) and *visceral* pain (heart, lungs, gastrointestinal or genitourinary system, or other deeper organs). The latter is diffuse and poorly localized, reflecting differences in innervation between somatic and visceral tissue. Somatosensory fibers are precisely located in the spinal cord and brain, whereas afferent viscerosensory fibers overlap each other and converge at several levels within the nervous system. Although some of the principles of pain management are relevant to visceral pain, in this chapter we concentrate on the management of chronic pain due to nociceptive pain of the somatic variety and neuropathic pain conditions. Together, these account for the majority of chronic pain conditions seen in clinical practice. Moreover, visceral pain is more commonly a harbinger of a serious underlying disorder with specific treatments targeting the disease itself rather than mere analgesia. In contrast, pain itself becomes the primary “disease” or target of therapy in a large proportion of chronic somatic and neuropathic pain disorders.

---

## Treatment of Pain

---

### Overview

The focus of this chapter is twofold. First, we discuss major classes of medications as they relate to pain management. Because a number of drugs are effective across multiple types of pain disorders, it is useful to consider them in a cross-cutting as well as a disease-specific fashion. Nonpharmacological treatments are also reviewed. In the following main section (“Selected Pain Disorders”), we briefly address several specific categories of disorders chosen because they 1) account for the most common types of chronic pain, 2) are conditions for which pain management is the principal focus, and 3) have been studied in numerous clinical trials. In short, prevalence, pain management as a priority rather than disease modification, and evidence-based therapy are the three selection criteria for the discussion of specific disorders. Even within these two broad foci (disorders and treatments), there will perforce be some intermingling. For example, certain drug classes have been heavily studied within certain pain disorders, and conversely, certain pain disorders have been a common target of several classes of medications or other treatments.

The prototypical diseases discussed are musculoskeletal disorders (principally fibromyalgia, low back pain, and osteoarthritis), headaches, and neuropathic pain. Musculoskeletal disorders account for more than two-thirds of pain-related outpatient visits, and headaches follow as the next most prevalent pain disorder. Neuropathic pain not only is prevalent but also is a popular target for clinical trials in pain management, and therefore is a common reason pain. Acute pain (e.g., injuries, postoperative pain), cancer pain, and visceral pain are not addressed. Although a moderate amount of thefor seeking U.S. Food and Drug Administration (FDA) approval of pain as a drug indication. Although pharmacotherapy receives the greatest attention in this chapter, we briefly review nonpharmacological treatments due to their important role in the management of chronic

information presented in this chapter is relevant to the treatment of pain in these and other conditions (especially the discussion of specific analgesics), a detailed discussion of these specialized topics is beyond the scope of this chapter.

## Strength of Evidence

The majority of the information in this chapter was derived from meta-analyses and systematic reviews. Individual randomized controlled trials (RCTs) are not presented unless they reported on a promising treatment for which multiple trials had not yet been performed. Certainly, evidence is strongest for those treatments that have shown efficacy in multiple trials rather than just a single RCT, particularly because individual trials sometimes yield contradictory findings. Uncontrolled or open-label studies provide still weaker evidence and are cited in only a few instances.

In meta-analyses and systematic reviews, the magnitude of a treatment's effect on particular domains such as pain and physical function is often reported as an *effect size*. The effect size is a standard way to determine the degree of improvement (or change) related to a particular therapy compared with a placebo or other type of control group. The effect size is calculated as the mean change in the treatment group minus the mean change in the control group, divided by the pooled standard deviation. By convention, an effect size of less than 0.2 is considered trivial; 0.2–0.5, small; 0.5–0.8, moderate; 0.8–1.2, important; and 1.2 or greater, very important ([Cohen 1998](#)).

Effect size can be useful when comparing continuous variables such as mean differences (e.g., in pain scores). When comparing response rates on a categorical variable (e.g., “improved” or “≥50% reduction in pain”), the *number needed to treat* (NNT) is another common metric. The NNT is calculated as the reciprocal of the absolute difference between treatment groups. For example, if a clinical trial demonstrates that 60% of subjects improve while taking a new analgesic versus 35% of subjects receiving a placebo, that is an absolute difference of 25%. The NNT is the reciprocal of that:  $1 \div 0.25 = 4$ . This means that for every four patients who receive the analgesic, one additional patient would achieve a therapeutic response over and above placebo (i.e., the other three patients may have done just as well taking the placebo). Actually, an NNT of  $\leq 5$  typically represents a reasonably good analgesic.

When studying the same pain condition, the NNT may also be useful in comparing different drugs. For example, in one study of acute pain after certain operative procedures, 10 mg of morphine, 30 mg of ketorolac, and 100 mg of meperidine (all administered by intramuscular injection) and 1,000 mg of acetaminophen (administered orally) all had NNTs between 3 and 4; furthermore, their 95% confidence intervals overlapped, implying no significant difference in the analgesic efficacy between intramuscular opioids, intramuscular nonsteroidal anti-inflammatory drugs (NSAIDs), and oral acetaminophen ([Barden et al. 2004](#)). However, analgesic effect may depend on the type of pain condition being treated or clinical context as well. For example, one study found that the NNT for acetaminophen after dental extraction was 3.8, compared with 1.9 after orthopedic surgery ([Barden et al. 2004](#)). Also, small sample sizes may affect the precision of NNT estimates; some feel that NNT calculations based on trial data involving fewer than 500 subjects should be interpreted cautiously. Second, it is more problematic to compare the NNTs of different drugs estimated from separate studies than to compare the NNTs estimated for different drugs tested in the same clinical trial. Third, NNTs derived from studying analgesics in acute pain conditions may not be readily generalizable to their efficacy in the treatment of chronic pain.

# Pharmacotherapy

## Nonopioid Analgesics

The anti-inflammatory properties of the extract of willow bark have been known for centuries. Salicylic acid was discovered as the extract's active ingredient in the nineteenth century and was subsequently acetylated to improve its gastrointestinal tolerability; acetylsalicylic acid became the prototypical analgesic aspirin. Aspirin and other related compounds constitute a class of drugs known as NSAIDs. All NSAIDs have three desirable pharmacological effects—anti-inflammatory, analgesic, and antipyretic. NSAIDs and acetaminophen are among the most commonly prescribed medications for acute and chronic pain and can also be obtained without a prescription.

Acetaminophen has analgesic and antipyretic effects similar to those of the NSAIDs but lacks a specific anti-inflammatory effect. Despite the widespread use of acetaminophen, its analgesic mechanism is poorly understood. Acetaminophen is a slightly weaker analgesic than NSAIDs (<10 point difference on a 100-point visual analog pain scale) (Lee et al. 2004; Towheed et al. 2006; Wegman et al. 2004) but is a reasonable first-line option because of its more favorable safety profile and low cost. A recent trial found acetaminophen to be no more effective than placebo in acute back pain (Williams et al. 2014), whereas a much earlier trial found acetaminophen to be equivalent to low- or high-dose ibuprofen in treating knee osteoarthritis (Bradley et al. 1991). It is possible that analgesic effectiveness may vary with type of pain condition, duration (acute vs. chronic), comparison group, and other factors. Acetaminophen is associated with asymptomatic elevations of aminotransferase levels at dosages of 4 g/day even in healthy adults, although the clinical significance of these findings is uncertain (Watkins et al. 2006). Thus, known liver disease is a reason either to use analgesics other than acetaminophen or to lower the acetaminophen maximum daily dosage to 2,000 mg or less.

NSAIDs block the enzymatic activity of cyclo-oxygenase (COX), which uses arachidonic acid to generate prostanoids. Prostanoids influence immune, cardiovascular, gastrointestinal, renovascular, pulmonary, central nervous system, and reproductive function. Although gastrointestinal adverse effects have traditionally been considered the most common and worrisome complication, cardiovascular risk has gained increasing attention (Antman et al. 2007). Aspirin was the first and at one time the most commonly used NSAID.

There are two major COX isoenzymes: COX-1 is expressed constantly in most tissues, whereas COX-2 is induced by inflammation. NSAIDs vary in their chemical structure and relative ability to block the COX-1 versus the COX-2 isoenzymes. Several prostaglandins are both hyperalgesic and gastroprotective. Thus, nonselective COX inhibition with NSAIDs like aspirin, ibuprofen, indomethacin, and naproxen, which inhibit both COX-1 and COX-2 enzymes, provides effective pain relief for inflammatory conditions but carries a risk for erosive gastritis and gastrointestinal bleeding. Selective COX-2 inhibitors (valdecoxib, rofecoxib, celecoxib) have less gastrointestinal toxicity because of the relative paucity of COX-2 expression in the gastrointestinal tract compared with inflammatory tissue. However, data from meta-analyses and registries have shown an increased risk of cardiovascular events and mortality from COX-2 use, particularly in patients with known cardiovascular disease who receive prolonged treatment. Rofecoxib (Vioxx) has been withdrawn from the market, and all COX-2 inhibitors should be used cautiously, if at all, in patients with cardiovascular disease or risk factors for cardiovascular disease. All NSAIDs, including nonselective COX inhibitors and COX-2 agents, appear equally effective in the

treatment of pain disorders ([Chou et al. 2006](#)). The NSAID that appears to be the safest in terms of cardiovascular risk is naproxen.

In July 2015, the FDA decided to strengthen its existing label warning that NSAIDs increase the chance of a heart attack or stroke. Although there is some risk even with short-term use or in patients without a history of cardiovascular (CV) disease or risk factors, both longer duration of use and presence of CV disease or risk factors substantially increase CV risk in patients receiving NSAIDs. However, the actual increased risk in a specific patient is still low, and given the prevalence of and disability associated with chronic pain and the limitations of other treatment options, NSAIDs are likely to remain a staple of pain management. Concerns about chronic use are particularly focused on special populations including those at greater risk of cardiovascular (e.g., known CV disease or >2 CV risk factors), gastrointestinal, or renal complications ([Marks et al. 2012](#)).

## Opioid Analgesics

The analgesic effects of opium have been known to mankind for more than 5,000 years. However, their inherent abuse risk soon became evident. Ever since, society has attempted to find a balance between licit and illicit use, therapeutic versus adverse effects, and medical needs and legal issues. Despite all the legal, administrative, and social interference, no other class of drugs has remained in use for as long as the opioids ([Schug 2005](#)).

Opioids have a leading place in the treatment of acute pain and advanced cancer pain of moderate to severe intensity, because in both instances treatment is expected to be of short to medium duration. In contrast, opioid treatment for chronic noncancer pain is frequently delayed until first- or second-line treatments have failed because of less clarity about the benefits of chronic use and greater concerns about addiction, long-term effects (e.g., immunological, reproductive), opioid-induced hyperalgesia, and regulatory difficulties.

The Controlled Substances Act of 1970 divided substances to be regulated into five schedules, as determined by the U.S. Drug Enforcement Administration. These schedules govern the legal distribution and use of most substances with a significant abuse liability. Schedule I drugs have the highest abuse potential; they are available for research only and have no approved medical uses. Schedule II–IV substances have decreasing abuse liabilities (II is the highest) and approved medical uses. Physicians are licensed to prescribe these compounds, and pharmacies can dispense them, although pharmacies do not stock all of these substances. Schedule II compounds have more stringent record-keeping and storage requirements than do Schedule III and Schedule IV substances. Schedule V substances have a recognized abuse liability (and approved medical uses) but are generally not as highly regulated vis-à-vis record keeping. Most opioids prescribed for pain are now Schedule II substances, and refills are not authorized; instead, each dispensation requires a new prescription. Exceptions are combination analgesics (e.g., those containing acetaminophen) that contain less than 90 mg of codeine per unit dose, which are Schedule III substances; and tramadol, which is a Schedule IV substance.

Opioids were initially reserved for the short-term treatment of pain following surgery, trauma, and other acute conditions as well as palliative therapy for cancer and other terminal diseases. In the 1990s, however, there was advocacy for improved treatment of chronic pain, which led to a more liberal use of opioids ([Franklin 2014](#); [Nuckols et al. 2014](#); [Rauenzahn and Del Fabbro 2014](#); [Reuben et al. 2015](#)). In the first decade of the twenty-first century, the number of opioid prescriptions increased by more than 60%. Opioids are now the leading cause of overdose deaths (about 16,000 deaths in the United

States annually) and are also associated with diversion to nonmedical uses. Because the long-term benefits of opioid therapy for chronic pain have not been well established, there are increasing state and federal regulations that are making the prescribing of opioids more onerous for both clinicians and patients. Nonetheless, many experts still believe that opioids have a role in that subset of patients whose chronic pain has been refractory to other treatments, as long as there is appropriate monitoring of response, attention to adverse effects, and minimization of diversion and abuse.

**Tramadol.** Tramadol is unique in that it has both opioid and nonopioid effects. Although its mode of action is not completely understood, it exerts an analgesic effect through binding to the  $\mu$  opioid receptor as an agonist (opioid effect) and weakly inhibiting the reuptake of serotonin and norepinephrine (nonopioid effect), similar to the effect of tricyclic antidepressants (TCAs). Tramadol is available in both short- and long-acting formulations. The starting dosage for the short-acting formulation is 50 mg once or twice daily, with gradual titration to a maximum of 400 mg/day. Dosage reduction is necessary in those with renal or hepatic disease. The risk of respiratory depression and, presumably, addiction is lower than with other opiates. However, it still should be used with some caution in persons recovering from substance use disorders. Dose reduction is recommended in older adult patients (>75 years) and in those with renal impairment (creatinine clearance <30 mL/minute) or cirrhosis of the liver. Multiple trials have demonstrated the efficacy of tramadol in pain disorders, particularly osteoarthritis, fibromyalgia, and neuropathic pain.

[Hollingshead et al. \(2006\)](#) conducted a systematic review of six trials evaluating tramadol in neuropathic pain. All four trials comparing tramadol with placebo showed benefit with tramadol: the NNT with tramadol versus placebo to reach at least 50% pain relief was 3.8. Single trials comparing tramadol with clomipramine or morphine were inconclusive.

In summary, the clinical trial evidence across a number of pain disorders is much stronger for tramadol, which has led to its recommendation as at least a second-line treatment for conditions such as osteoarthritis, fibromyalgia, and neuropathic pain. Because it is a Schedule IV medication, tramadol may be an appropriate option when other analgesics have failed and before initiating other opioid analgesics, all of which are Schedule II.

**Efficacy of opioids.** [Furlan et al. \(2006\)](#) conducted a meta-analysis of opioid use for chronic noncancer pain. Included were 41 trials involving 6,019 patients: 80% of the patients had nociceptive pain (osteoarthritis, rheumatoid arthritis, or back pain); 12%, neuropathic pain (postherpetic neuralgia, diabetic neuropathy, or phantom limb pain); 7%, fibromyalgia; and 1%, mixed pain. For certain analyses, the authors classified opioids as weak (propoxyphene, tramadol, codeine) or strong (all other opioids). Tramadol was the agent studied in 17 trials (3,433 patients), propoxyphene or dextropropoxyphene in 3 trials (1,074 patients), codeine in 7 trials (444 patients), oxycodone in 6 trials (517 patients), and morphine in 8 trials (551 patients). Average duration of treatment was 5 weeks (range, 1–16 weeks). On average, 33% of patients in the opioid groups dropped out (15% because of inadequate pain relief and 21% because of side effects; some patients reported both reasons), as did 38% in the placebo groups (30% because of inadequate pain relief and 10% because of side effects).

Opioids were more effective than placebo for both pain and functional outcomes in patients with nociceptive or neuropathic pain. The only opioid studied for fibromyalgia was tramadol (two trials, 228 patients), where it proved effective. The effect size for opioids

compared with placebo was moderate for pain ( $-0.60$ ) and small for functional outcomes ( $-0.31$ ). Only eight trials compared opioids with other analgesics; in these trials, opioids did not differ significantly from nonopioids in terms of pain relief (effect size,  $-0.05$ ) and were significantly worse than nonopioids in terms of functional outcomes, although only slightly so (effect size,  $0.16$ ). The authors concluded that the strong opioids (oxycodone, morphine) were significantly more effective than other drugs (effect size,  $-0.34$ ), but this assessment was based on only two trials, one of which was an open-label study ([Furlan et al. 2006](#)).

A systematic review reported on 11 studies (2,877 patients) that assessed quality of life in patients with chronic nonmalignant pain who were receiving long-term opioid treatment ([Devulder et al. 2005](#)). Six studies were randomized trials, and five were observational studies. Of the four trials in which baseline values were reported, three showed an improvement in quality of life. Similarly, quality of life improved in four of the five observational studies. Although these results suggest potential quality-of-life benefits from opioid long-term treatment, the authors concluded that further methodologically rigorous studies were needed to confirm the findings and to elucidate the potential adverse effects of physical tolerance, withdrawal, and addiction on functional status.

**Adverse effects.** [Moore and McQuay \(2005\)](#) conducted a systematic review of 34 trials with 4,212 patients that provided information on adverse events related to opioid use in treating noncancer pain. Most opioids used (accounting for 90% of patients) were for treating moderate rather than severe pain. Dry mouth (affecting 25% of patients), nausea (21%), and constipation (15%) were the most common adverse events. A substantial proportion of patients taking opioids (22%) withdrew because of adverse events. Because most trials were short ( $<4$  weeks) and did not use titrated doses, the implications for long-term use in clinical practice are less certain. [Eisenberg et al. \(2006\)](#) also reported on adverse events in their systematic review of opioids for neuropathic pain. Compared with placebo recipients, opioid recipients had higher rates of nausea (33% vs. 9%), constipation (33% vs. 10%), drowsiness (29% vs. 12%), dizziness (21% vs. 6%), and vomiting (15% vs. 3%). Among studies reporting causes of withdrawal, more patients receiving opioids withdrew because of adverse effects (11% vs. 4%). Finally, in the review by [Furlan et al. \(2006\)](#), only three side effects occurred significantly more frequently with opioids than with placebo: nausea, constipation, and somnolence. These rates were 14%, 9%, and 6% higher in opioid recipients, respectively.

A large population-based study from Denmark found that opioid usage was significantly associated with more severe pain, poorer self-rated health, lower quality of life, less physical activity, lower employment, higher levels of health care utilization, and more subjects living alone ([Højsted and Sjøgren 2007](#)). The cross-sectional nature of the study does not prove causation, and it is certainly possible that the opioid users would have fared worse without opioid treatment. However, it does raise questions of whether opioid treatment of chronic pain is achieving the key goals of pain relief, improved functional status, and better quality of life.

Studies have indicated that endocrinological abnormalities such as hypogonadism and erectile dysfunction may be associated with opioid therapy ([Ballantyne and Mao 2003](#); [Daniell 2002](#)). In women, opioid use has been associated with amenorrhea and decreased sex hormone levels ([Daniell 2008](#)). Two small trials evaluating opioid use in chronic pain reported analyzable data regarding sexual activity, and both found that patients taking opioids had better self-reported sexual function than those taking placebo ([Furlan et al. 2006](#)). Improvement of well-being secondary to better pain control may account for this.

Clearly, the incidence and clinical significance of opioid-related hypogonadism need to be better defined.

A feared consequence of long-term opioid use is cognitive dysfunction. Studies have suggested that opioid treatment for chronic pain may be associated with impaired neuropsychological performance regarding reaction times, psychomotor speed, and working memory (Højsted and Sjøgren 2007). However, many other factors may be playing a role, including pain itself, concomitant medications, and psychiatric comorbidity. A systematic review concluded that stable doses of opioids do not impair driving performance (Fishbain et al. 2003).

A recent systematic review on long-term opioid treatment (>3 months) for chronic pain reported the following conclusion:

No study of opioid therapy versus no opioid therapy evaluated long-term (>1 year) outcomes related to pain, function, quality of life, opioid abuse, or addiction. Good- and fair-quality observational studies suggest that opioid therapy for chronic pain is associated with increased risk for overdose, opioid abuse, fractures, myocardial infarction, and markers of sexual dysfunction, although there are few studies for each of these outcomes; for some harms, higher doses are associated with increased risk. Evidence on the effectiveness and harms of different opioid dosing and risk mitigation strategies is limited. (Chou et al. 2015b, p. 276)

**Tolerance and addiction.** The risks of prescription opioid addiction, abuse, and diversion among chronic pain patients are not well understood. In part, this is due to inconsistent use of terminology and the difficulty of defining *addiction* and *abuse* in patients receiving opioids for chronic pain (Heit 2003; Savage et al. 2003). The term *dependence* is particularly problematic because confusion can occur between physical dependence, psychological dependence, and substance dependence (as defined in DSM-IV-TR [American Psychiatric Association 2000]). Some experts believe that the term *addiction* should be reserved for the specific condition defined as substance dependence in DSM-IV-TR. *Misuse* describes other problematic opioid use, including DSM-IV-TR substance abuse and other nontherapeutic uses that do not meet DSM-IV-TR criteria. *Diversion* includes selling, sharing, and trading of prescription opioids.

A systematic review of the literature on the risk of iatrogenic addiction in patients treated with opioids for acute and subacute pain yielded 41 eligible articles (Wasan et al. 2006). However, there were no randomized trials or comparative longitudinal studies, and the results of nine studies of low methodological quality yielded conflicting findings. The authors concluded that it is not known whether the risk for iatrogenic addiction among patients treated for acute or subacute pain is relatively high (>10%) or low (<0.1%).

In a 10-year follow-up study of patients treated with opioids for chronic pain, tolerance was not a problem in the majority of patients (Jensen et al. 2006). In contrast, a retrospective study of 104 chronic pain patients younger than 50 years and 102 patients older than 60 years showed that younger patients and those with nociceptive pain (as compared with neuropathic pain) had much higher escalation of opioid doses over a 15-month follow-up period (Buntin-Mushock et al. 2005). Another worrying finding of this study was that although the younger patients had a dosage increase of 640% (from 49 to 365 mg/day of morphine equivalent) during the observation period, the pain visual analog scale scores did not change at all. Although this does not mean that addiction is playing an important role, it does suggest that decisions about dose escalation may need to vary depending on the type of pain, patient age, treatment response, and other factors. Failure of pain to improve with moderate dosage increases in an individual patient may indicate that opioids are not the optimal treatment rather than that continuing dose escalations are needed. Some experts have classified patients or pain syndromes as opioid responsive

versus opioid resistant (Smith 2005). Indeed, some patients may develop opioid-induced hyperalgesia where the balance between anti-nociceptive and pro-nociceptive systems is upregulated after opioid exposure, leading to an enhanced vulnerability to pain (Angst and Clark 2006; Højsted and Sjøgren 2007).

Højsted and Sjøgren (2007) reviewed some important predictors of opioid use. The “rush” the patient experiences after administration of an opioid is caused by a rapid and large increase in dopamine in the brain reward system. Important factors for abuse liability associated with the drug include the speed of access and the concentration at the target sites. On a scale of opioid attractiveness, sustained-release oxycodone had the highest rating and the fentanyl patch had the lowest score; oral transmucosal fentanyl, methadone, and sustained-release morphine had intermediate scores. However, research demonstrating the higher abuse potential of one opioid versus another is limited. Risk factors for opioid abuse in patients with chronic pain are young age, male gender, past alcohol or cocaine abuse, previous drug conviction, mental health disorders, pain in multiple regions, and pain after motor vehicle accidents.

A randomized trial of 11,352 participants with chronic noncancer pain compared the abuse potential of tramadol, NSAIDs, and hydrocodone (Adams et al. 2006). Abuse was defined by an algorithm as including increasing doses without physician approval, use for purposes other than the ones intended, inability to stop using the drug, and withdrawal. The percentage of subjects who scored positive for abuse at least once during the 12-month follow-up period was 2.5% with NSAIDs, 2.7% with tramadol, and 4.9% with hydrocodone. When more than one algorithm criterion was required, abuse rates were 0.5% with NSAIDs, 0.7% with tramadol, and 1.2% with hydrocodone. Although the authors concluded that the prevalence of abuse/dependence was significantly lower with NSAIDs and tramadol than with hydrocodone, the rates overall are quite low and the between-group differences are rather small.

**General principles of opioid use.** The use of very high doses of opioids is rarely helpful. Purely on the basis that the highest daily dosage of opioids used in existing trials is 180 mg of morphine or its equivalent, opioid reduction or rotation should be considered at this point. More conservative recommendations favor staying under 100 mg morphine equivalent daily dose in most patients. Because of incomplete cross-tolerance (i.e., patients may be tolerant to high doses of the first opioid yet have a lower tolerance to the new opioid), the initial dosage of a new opioid should be equivalent to 50% or less of the dosage of the original opioid. Equianalgesic doses of oral and transdermal opioids are summarized in Table 54-1. When trials of several opioids are ineffective in chronic pain, it is appropriate to consider weaning patients off the drug and discontinuing its use. Weaning can usually be accomplished over 10 days, but the exact weaning schedule depends on dose, drug, and duration of treatment. In cases of addiction, referral to an addiction specialist may be preferable to drug discontinuation. Opioids are often best used as an adjunctive treatment—and in recent guidelines as a last resort (Chou et al. 2014; Dowell et al. 2016)—rather than as the sole therapy for chronic pain. Before starting opioid therapy, patients should understand that the goal of treatment is not the complete elimination of pain but a 25%–50% reduction in its intensity and improvement in mood and functioning.

**TABLE 54-1. Oral and transdermal opioid analgesic equivalence**

Drug	Dose (mg)	Duration (hours) <sup>a</sup>
------	-----------	-------------------------------

Drug	Dose (mg)	Duration (hours) <sup>a</sup>
Morphine	30	2–4
Codeine	200 <sup>b</sup>	3–4
Hydrocodone	30–40 <sup>c</sup>	4–6
Oxycodone	20	4–4
Hydromorphone	7.5	4–4
Meperidine	300 <sup>b</sup>	4–4
Methadone	20 <sup>d</sup>	4–8
Fentanyl (transdermal)	12.5 µg/hour <sup>e</sup>	48–72

<sup>a</sup>Duration of analgesia is dose-dependent; the higher the dose, usually the longer the duration.

<sup>b</sup>These high doses of codeine and meperidine are not recommended clinically.

<sup>c</sup>Equianalgesic data are more variable for hydrocodone than for most other opioids.

<sup>d</sup>For opioid-tolerant patients converted to methadone, starting doses should be 10%–25% of the equianalgesic dose. Also, the half-life of methadone can vary widely, from 12 to 190 hours.

<sup>e</sup>1 µg/hour transdermally is approximately equal to morphine 2 mg/24 hours orally.

A review of 13 guidelines addressing opioid prescribing in adults with chronic pain (Nuckols et al. 2014) found that most guidelines recommend that clinicians should 1) avoid doses greater than 90–200 mg of morphine equivalents per day (ideally less than 100 mg); 2) have additional knowledge to prescribe methadone (as well as buprenorphine); 3) recognize risks of fentanyl patches, titrate cautiously, and reduce doses by at least 25%–50% when switching opioids; and 4) use opioid risk assessment tools, written treatment agreements, and urine drug testing to mitigate risks. However, most recommendations are supported by observational data or expert consensus rather than findings from clinical trials. Principles for the use of opioids in chronic pain are summarized in Table 54-2.

**TABLE 54-2. Opioid management strategy for treatment of chronic pain**

1. Maximize non-opioid analgesic strategies first (i.e., a “delayed” opioid approach).
  2. Inform subjects of risks, including addiction, before initiating opioid therapy.
  3. Although the evidence is not strong, four strategies are either encouraged by some expert pain groups or mandated by prescribing regulations in some states:
    - a. Opioid risk tools: Stratify risk with screening measures such as Opioid Risk Tool (ORT) and Screener and Opioid Assessment for Patients with Pain (SOAPP).
    - b. Opioid agreements (contracts): Facilitate the use of opioid agreements (contracts) for patients initiating or increasing opioids. Key points include stipulating the frequency of obtaining medications, timely refills but no early replacement for lost or stolen prescriptions, safe storage, no sharing, single-source prescribing, monitoring through urine screens, and adherence to monitoring visits.
    - c. Urine drug screening (UDS): Conduct initial and periodic UDS for opioids as well as illicit drugs.
    - d. Prescription Drug Monitoring Program (PDMP): Use the state PDMP to monitor all sources of controlled substances.
  4. Immediate-release opioids are recommended for initial therapy and breakthrough pain, although sustained-released opioids may have an important role in long-term therapy.
  5. Short-acting opioid dose is typically 10%–20% of total daily dose (e.g., if 24-hour scheduled morphine totals 50 mg, give 5–10 mg short-acting morphine for breakthrough pain).
  6. Schedule follow-up visits at 2- to 3-month intervals, performing periodic urine testing to confirm adherence.
  7. Monitor pain severity and pain-related functional impairment at follow-up visits, because analgesic response may wane in some patients over time.
  8. Avoid opioid dose escalations without first assessing pain severity and interference.
  9. View opioid initiation as an empirical trial. Consider discontinuing opioids if not beneficial.
  10. Consider opioid rotation if tolerance to one opioid is suspected. When doing so, consider reducing morphine-equivalent dose (MED) of new opioid by 30%–50% to accommodate for unknown cross-tolerance and then titrate to goal.
  11. If patient is a high-risk candidate for opioids (particularly those with a current or past substance use disorder including alcohol or drugs or with psychiatric comorbidity such as depression), consider referral to a pain specialist.
  12. Minimize use of sedative-hypnotics, benzodiazepines, and other controlled substances.
  13. Consider referral to pain specialty program if MED exceeds 80–120 mg/day.
- 

*Source.* Adapted from [Chou et al. 2014](#); [Dowell et al. 2016](#); [Nuckols et al. 2014](#); [Reuben et al. 2015](#).

**Long-acting opioids.** A systematic review ([Carson et al. 2011](#)) compared the effectiveness and harms of long-acting opioids and of long-acting opioids compared with short-acting opioids in adults with chronic noncancer pain. Although the authors identified 10 head-to-head trials comparing two or more long-acting opioids, the evidence was insufficient to determine if there are differences among long-acting opioids in effectiveness or harms. The 8 high-quality trials found no difference in pain relief or functional outcomes between long-acting opioids. Evidence was insufficient to determine if long-acting opioids as a class are more effective or are associated with fewer harms than short-acting opioids.

**Methadone.** The principal use of methadone has been as a maintenance drug to prevent withdrawal in opioid-addicted adults. The stigma as a “drug for addicts” has been one factor limiting its use as an analgesic in clinical practice. It has gained increased use in the treatment of intractable pain in end-of-life care and other palliative care settings. Concerns regarding use of methadone for pain relate to its long and unpredictable half-life and the associated risk of a delayed overdose. Furthermore, there are large individual variations in presumed equianalgesic doses of methadone relative to other opioids. This prevents the use of simple equianalgesic tables to calculate the required dose of methadone during rotation from other opioids.

Although methadone has increasingly been used for the treatment of chronic noncancer pain, published data are rather modest. In a literature review of 21 studies, only 1 small randomized trial ( $N=19$ ) was found; the remainder were either cases series ( $N=7$ ) or case reports ( $N=13$ ) ([Sandoval et al. 2005](#)). Methadone was administered primarily when previous opioid treatment was ineffective or poorly tolerated. Thus, the evidence base is currently inadequate and does not support a first-line role for methadone in chronic pain therapy.

Regarding safety, a review of 168 studies ([Weimer and Chou 2014](#)) found insufficient evidence for most safety questions, including risk factors associated with methadone-overdose deaths and adverse events, the comparative mortality of methadone versus other opioids, the harms associated with methadone use during pregnancy, and the effects of risk-mitigation strategies such as electrocardiogram monitoring, strategies for managing patients with prolonged QTc intervals on screening, urine drug testing, alternative dosing regimens for initiation and titration of therapy, and timing of follow-up.

**Buprenorphine.** Buprenorphine was introduced into the United States in 1985 as an opioid analgesic and like other opioids was found to have the potential to be intravenously abused ([Chen et al. 2014](#)). To address this issue, naloxone (an opioid receptor antagonist) was added, and the combination buprenorphine-naloxone (bup/nal; Suboxone) was approved by the FDA in 2002 as a Schedule III drug for office-based addiction treatment. Compared with other opioids, buprenorphine has somewhat lower addiction potential, fewer side effects, and a longer duration of action. The low dose of naloxone contained in bup/nal can reverse opioid side effects such as respiratory depression, sedation, and hypotension without significantly reversing analgesia. In 2007, the World Health Organization recognized buprenorphine and bup/nal as a treatment for opioid dependence. By 2011, there had been more than 7 million buprenorphine-related prescriptions in the United States alone, with the majority of these being for bup/nal. It remains unclear whether bup/nal is superior to methadone for maintenance therapy in opioid-addicted patients.

Bup/nal is a sublingual combination tablet composed of buprenorphine and naloxone in a fixed 4:1 ratio. Although FDA approved only for addiction treatment, bup/nal has been increasingly used off-label as a treatment for chronic pain. This is particularly the case for patients currently or previously on opioids who have developed tolerance or, alternatively, addiction problems. One potential mechanism for its analgesic efficacy in opioid-tolerant patients may be reversal of opioid-induced hyperalgesia. The rationale for bup/nal’s use in opioid-naïve chronic pain patients is less clear, since its unique pharmacological properties make bup/nal a relatively weak analgesic. Finally, buprenorphine and bup/nal prescribing is currently restricted to clinicians with special credentialing. For all of these reasons, more research is needed before bup/nal becomes a mainstream treatment for chronic pain.

## Antidepressants

### Tricyclic antidepressants and selective serotonin reuptake inhibitors.

TCAs have the longest track record in the treatment of multiple pain conditions. Typically, lower dosages of TCAs have been used in clinical trials of pain management (e.g., 25–100 mg of amitriptyline or equivalent) compared with the dosages usually necessary for treating depression. Advantages of TCAs include good evidence from multiple clinical trials, decades of clinical experience with TCAs in pain management, and the low cost of these generic agents. Disadvantages include the side effects associated with TCAs (which may be less, however, when prescribing the lower doses used for analgesia), including worrisome cardiovascular side effects (e.g., hypertension, postural hypotension, arrhythmias) and a risk of falling in elderly patients, and potential lethality in overdoses.

A meta-analysis of 96 RCTs evaluating antidepressants for the treatment of conditions manifested by somatic symptoms (the majority involving painful symptoms) included 55 TCA trials, of which 76% showed benefits; 28 trials using antiserotonin agents (principally headache trials using mianserin, a drug approved in Europe but not in the United States), of which 57% showed benefits; and 17 trials using selective serotonin reuptake inhibitor (SSRI) antidepressants, of which 47% showed positive results (O'Malley et al. 1999). Only a few trials were head-to-head comparisons of two antidepressants. Indirect comparisons did not show a significant difference by type of antidepressant using meta-regression, but TCAs were superior to SSRIs ( $P < 0.02$ ) using a bivariate tally procedure. Admittedly, such statistical comparisons are not as conclusive as direct comparisons of antidepressants within the same trial. Another review concluded that SSRIs appeared to have a relatively weak effect in ameliorating chronic pain (Jung et al. 1997).

**Serotonin-norepinephrine reuptake inhibitors.** *Duloxetine.* A review of 30 trials in patients with diabetic neuropathy (12 trials), fibromyalgia (9 trials), low back pain (6 trials), and osteoarthritis (3 trials) found that the serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressant duloxetine 60 mg once daily was effective in reducing pain in all four conditions (Pergolizzi et al. 2013). Duloxetine showed a rapid onset of action, with separation from placebo beginning at week 1. In a number of trials, both patients with depression and those without depression were enrolled, although path analysis estimated that more than two-thirds of the analgesic effect in duloxetine-treated patients was attributable to a direct analgesic effect, with less than one-third possibly explained by an antidepressant effect (Brannan et al. 2005; Brecht et al. 2007; Perahia et al. 2006; Marangell et al. 2011). Two trials in low back pain found no differential efficacy of duloxetine over placebo between patients who were using concomitant NSAIDs or acetaminophen and those who were not (Skljarevski et al. 2012). Two trials in osteoarthritis found that efficacy was similar in older and younger patients, and that increasing the dosage to 120 mg in nonresponding patients did not provide additional benefit (Micca et al. 2013). Meta-analyses comparing duloxetine and paroxetine have not shown differing effects on pain, although a number of these trials were conducted in depressed patients without high levels of pain at baseline (Krebs et al. 2008; Thaler et al. 2012).

*Milnacipran.* Approved some years ago in Europe for the treatment of depression, milnacipran is comparable to SSRIs as an antidepressant (Papakostas and Fava 2007). Although milnacipran is FDA approved only for treatment of fibromyalgia, levomilnacipran (an enantiomer of milnacipran) is FDA approved for treatment of depression. Substantial data (five trials involving 4,138 participants) confirm the effectiveness of milnacipran 100

mg or 200 mg for fibromyalgia, although there are not adequate data to demonstrate its efficacy for neuropathic pain ([Derry et al. 2012](#)) A meta-analysis of 5 milnacipran trials (4,129 patients), 4 duloxetine trials (1,411 patients), and 10 amitriptyline trials (612 patients) showed all three drugs to be superior to placebo, with small differential effects of the drugs on several fibromyalgia symptoms but overall similar acceptability and effectiveness ([Häuser et al. 2011](#)). However, the methodological quality of the amitriptyline trials was poor compared with that of the trials of the other two drugs.

*Venlafaxine.* There is only modest evidence for the efficacy of venlafaxine in treating fibromyalgia—four open-label cohort studies and one randomized trial ([VanderWeide et al. 2015](#))—and no rigorous studies in any other pain condition. Thus, while clinically used in treating pain, venlafaxine is not FDA approved for any pain disorder.

**Other antidepressants.** Mirtazapine was studied in a 6-week open-label trial of 594 patients with a primary diagnosis of at least one chronic pain syndrome ( $\geq 3$  months) and a clinical diagnosis of depression ([Freynhagen et al. 2006](#)). The mean daily dose was  $35 \pm 10$  mg at study endpoint, and a statistically significant reduction in pain ( $P < 0.0001$ ) was found. Pain improvement was not related to age or type of pain syndrome.

## Anticonvulsants

Anticonvulsant drugs have been used in the management of pain since the 1960s. The clinical impression is that they are useful for chronic neuropathic pain, especially when the pain is lancinating or burning. Three of the most extensively studied anticonvulsants are gabapentin, pregabalin, and carbamazepine. Gabapentin and pregabalin have the strongest evidence for the treatment of pain. These two *gabapentinoids* act as neuromodulators by selectively binding to the  $\alpha_2\delta$ -subunit protein of calcium channels in various regions of the brain and the superficial dorsal horn of the spinal cord. This results in inhibition of the release of excitatory neurotransmitters that are important in the production of pain. Gabapentin and pregabalin are analogs of  $\gamma$ -aminobutyric acid (GABA), but they have no activity at GABA receptors and do not alter GABA uptake or degradation.

**Gabapentin.** A systematic review of 15 trials (1,468 participants) evaluating gabapentin included 1 acute pain trial and 14 trials involving neuropathic pain (7 studies of diabetic neuropathy, 2 of postherpetic neuralgia, and 1 each of cancer-related neuropathy, phantom limb pain, spinal cord injury, Guillain-Barré syndrome, and miscellaneous neuropathies) ([Wiffen et al. 2005a](#)). In the 14 chronic neuropathic pain trials, 42% of participants improved taking gabapentin versus 19% taking placebo, and the NNT for improvement in all trials with evaluable data was 4.3 (95% CI=3.5–5.7). Withdrawal rates were 14% for gabapentin versus 10% for placebo. The study of acute postoperative pain (70 patients) showed no benefit for gabapentin. Thus, there is good evidence that gabapentin is more effective than placebo in the treatment of chronic neuropathic pain.

**Pregabalin.** Pregabalin is a novel compound that has analgesic, anticonvulsant, and anxiolytic effects ([Shneker and McAuley 2005](#)). In 19 studies involving 7,003 participants, pregabalin at doses of 300 mg, 450 mg, and 600 mg daily was effective in patients with postherpetic neuralgia, painful diabetic neuropathy, central neuropathic pain, and fibromyalgia ([Moore et al. 2009](#)). Pregabalin at 150 mg daily was generally ineffective. Regarding fibromyalgia specifically, six trials (2,242 participants) have demonstrated the efficacy of pregabalin and gabapentin for fibromyalgia, but most of the trials (five of the six) studied pregabalin ([Häuser et al. 2009](#)). Whereas both pregabalin and gabapentin are

FDA approved for neuropathic pain, only pregabalin is approved for fibromyalgia. Pregabalin, gabapentin, and duloxetine have similar efficacy for diabetic neuropathic pain ([Quilici et al. 2009](#)). Pregabalin is also approved as an adjunctive therapy for adults with partial-onset seizures. The U.S. Drug Enforcement Administration has placed pregabalin in Schedule V of the Controlled Substance Act (indicating a low potential for abuse), possibly because of withdrawal symptoms that were found during clinical trials. The most common adverse events are related to the central nervous system and include somnolence, dizziness, and peripheral edema. Dose-related weight gain can occur and is highest at a dosage of 600 mg/day. For pain disorders, the usual dosage is 300–450 mg/day, administered in twice-daily doses.

**Carbamazepine.** A systematic review of 12 trials (404 participants) included 4 placebo-controlled trials of trigeminal neuralgia, of which 2 with evaluable data yielded an NNT of 1.8 (95% CI=1.4–2.8) ([Wiffen et al. 2005b](#)). For diabetic neuropathy the data were insufficient to calculate an NNT. There was no evidence that carbamazepine was effective for acute pain. In summary, carbamazepine appears effective for trigeminal neuralgia, but the amount and quality of evidence for gabapentin and pregabalin are stronger for other types of neuropathic pain.

**Other anticonvulsants.** Systematic reviews have revealed a lack of analgesic efficacy for either phenytoin or clonazepam ([Birse et al. 2012](#); [Corrigan et al. 2012](#)).

## Other Pharmacological Agents

**Skeletal muscle relaxants.** Most skeletal muscle relaxants are approved by the FDA for treating either spasticity (baclofen, dantrolene, and tizanidine) or musculoskeletal pain (carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine) ([Chou and Peterson 2005](#)). There is insufficient evidence to prove that skeletal muscle relaxants differ in their efficacy, adverse events, or safety. Most trials have focused on acute rather than chronic pain. Cyclobenzaprine has been studied in several fibromyalgia trials and is discussed further in the “Fibromyalgia” section (under “Pharmacotherapy”). Indeed, cyclobenzaprine is the best-studied muscle relaxant in musculoskeletal disorders overall; in 21 fair-quality trials, it has consistently proven superior to placebo for relieving pain, reducing muscle spasms, and improving functional status. Cyclobenzaprine 5-mg doses are equally as effective as 10-mg doses (each given three times a day) but cause fewer side effects. Also, 20-mg doses (thrice daily) are not more effective than 10-mg doses and cause more side effects.

**Topical analgesics.** A potential advantage of topical agents is avoidance of the systemic side effects often associated with oral medications. Disadvantages are that only localized areas of pain can be effectively treated and that irritating skin reactions occur in a minority of patients. Several topical analgesics—lidocaine, capsaicin, and salicylate—have been studied in multiple trials. Postherpetic neuralgia is an FDA-approved indication for the lidocaine 5% patch, which is discussed in more detail in the “Neuropathic Pain” section. In a meta-analysis of systemic administration of local anesthetics for neuropathic pain, [Tremont-Lukats et al. \(2005\)](#) reviewed 19 studies (706 patients total; 10 trials of lidocaine and 9 trials of mexiletine, an antiarrhythmic agent that is also used off-label for pain). Lidocaine (most commonly 5 mg/kg administered intravenously over 30–60 minutes) and mexiletine (median dosage: 600 mg/day administered orally) were similar in efficacy and tolerance to morphine, amitriptyline, and gabapentin. However, the effects of

parenteral lidocaine are short lived, and mexiletine is not yet widely used or recommended as first- or second-line therapy.

Capsaicin is an alkaloid derived from chili peppers that acts on vanilloid type 1 receptors; repeated application of capsaicin is thought to desensitize cation channel receptors, leading to depletion of substance P from primary afferent neurons ([Chong and Hester 2007](#)). The main disadvantage of capsaicin is the initial burning sensation, which may persist for days. Capsaicin must be applied three to four times per day over the entire painful area for up to 8 weeks before optimal pain relief can be achieved. [Mason et al. \(2004a\)](#) reviewed the clinical trial evidence for using capsaicin to treat chronic pain. Six double-blind, placebo-controlled trials (656 patients) were pooled for analysis of neuropathic conditions, and three double-blind, placebo-controlled trials (368 patients) were pooled for analysis of musculoskeletal conditions. In patients with neuropathic pain, 57% of patients achieved at least 50% pain relief with capsaicin versus 42% of patients taking placebo. In patients with musculoskeletal conditions, the response rates were 38% versus 25%. Approximately one-third of patients experienced local adverse events with capsaicin. The authors concluded that capsaicin has moderate to poor efficacy in the treatment of chronic musculoskeletal or neuropathic pain but may be useful as an adjunctive therapy or sole therapy for a small number of patients who are unresponsive to, or intolerant of, other treatments.

The same authors also reviewed the evidence for topical salicylates ([Mason et al. 2004b](#)). In three trials evaluating 182 patients with acute conditions, topical salicylates were significantly more efficacious in relieving pain than placebo (NNT=2.1; 95% CI=1.7-2.8). In six trials evaluating 429 patients with chronic conditions, topical salicylates were also better than placebo (NNT=5.3; 95% CI=3.6-10.2). However, larger, more rigorous trials tended to have negative results. Based on limited information, the authors concluded that topical salicylates may be efficacious in the treatment of acute pain, although trials of its use in treating musculoskeletal and arthritic pain suggested moderate to poor efficacy. Finally, systematic reviews ([J. Lin et al. 2004](#); [Mason et al. 2004c](#)) as well as an RCT suggest that topical NSAIDs may be beneficial (ibuprofen for osteoarthritis of the knee has been studied the most) ([Underwood et al. 2008](#)).

**Cannabinoids.** The presence of specific high-affinity cannabinoid type 1 (CB<sub>1</sub>) receptor binding sites has been demonstrated in the central nervous system and in certain peripheral tissues, whereas CB<sub>2</sub> receptors are expressed in high quantities in immune tissues and cells. Two main endogenous cannabinoids have been described, and their role in modulating pain has been increasingly recognized. The social stigma associated with cannabinoids and the politicolegal issues related to cannabis use for medical purposes have been barriers to research. However, advocacy for increased legalization in the United States might prompt further research and clinical use for chronic pain.

There are two FDA-approved cannabinoids (dronabinol and nabilone) for chemotherapy-associated nausea and vomiting and appetite stimulation in wasting illnesses. A recent review of all types of cannabinoids (FDA-approved drugs, medical marijuana, and other preparations) found 6 trials (325 patients) investigating chronic pain, 6 trials (396 patients) examining neuropathic pain, and 12 trials (1,600 patients) focused on multiple sclerosis ([Hill 2015](#)). Several of the trials had positive results, suggesting potential benefits for these indications. However, the heterogeneous preparations in which cannabinoids are available and can be ingested (both legal and illicit) make consistent product quality, dosing, and potential efficacy as well as adverse events rather unpredictable. For example, only 6 published trials (226 patients) have investigated smoked or vaporized marijuana for

chronic noncancer pain; 5 of the trials focused on neuropathic pain and, while showing short-term benefits, had substantial methodological shortcomings, including inadequate blinding ([Deshpande et al. 2015](#)). Moreover, the long-term psychoactive and neurocognitive effects of medical marijuana remain unknown.

## Nonpharmacological Treatments

Nonpharmacological treatments will not be discussed in detail but need to be mentioned because of their important role in the management of chronic pain. Medications are typically targeted to the symptoms, but dysfunctional beliefs, attitudes, coping styles, and behaviors frequently develop in patients with chronic pain and contribute to its perpetuation and their disability. Moreover, just as in other chronic medical disorders, pharmacotherapy is necessary but not sufficient for optimizing outcomes. For example, the patient with diabetes not only needs insulin or other hypoglycemic drugs but also requires dietary changes, exercise, and other lifestyle modifications to achieve target blood glucose levels. Cognitive-behavioral therapy, pain self-management, and exercise are among the most evidence-based approaches and are discussed below, along with several other behavioral interventions. [Table 54-3](#) summarizes the level of evidence for a variety of nonpharmacological interventions in the treatment of chronic pain.

## Psychotherapy and Behavioral Interventions

**Cognitive-behavioral therapy.** Cognitive-behavioral therapy (CBT) has by far the largest body of evidence supporting its effectiveness in the treatment of various types of chronic pain disorders. [Kroenke and Swindle \(2000\)](#) reviewed 31 trials of CBT for the treatment of somatic syndromes, of which more than half involved pain conditions, including 5 trials of back pain, 3 of irritable bowel syndrome, 3 of noncardiac chest pain, 2 of fibromyalgia, and 4 of other pain disorders. Most of those trials (14 of 17) involving pain disorders found CBT to be beneficial. An update of this review found additional studies confirming the effectiveness of CBT ([Jackson et al. 2006](#)). Also, a systematic review of treatment for somatoform disorders (in which multiple pain symptoms are often present)

found that CBT was effective in 11 of 13 RCTs (Kroenke 2007). Both group CBT and individual CBT appeared to be effective, as did briefer courses of CBT (e.g., 3–6 sessions). When administered for pain and other somatic disorders, it is important that CBT be *somatically focused*, having a somewhat different orientation than CBT provided for depressive and anxiety disorders. Patients with chronic pain and other somatic syndromes present with physical rather than psychological symptoms and often attribute their symptoms to physical disorders (i.e., medical factors). Thus, the mental health professional accustomed to providing CBT for psychiatric disorders may require some additional training in CBT appropriate for treating chronic pain and other somatic syndromes.

**Pain self-management programs.** Pain self-management (PSM) programs that emphasize self-efficacy have consistently demonstrated effectiveness in improving health outcomes and reducing health care utilization among patients with arthritis and various rheumatic conditions (Du et al. 2011; Institute of Medicine 2011; McBeth et al. 2012; Warsi et al. 2003). Self-management for both acute (Damush et al. 2003) and chronic (Von Korff and Moore 2001) low back pain has also proven effective. Indeed, CBT and PSM are the two best-established psychobehavioral approaches to treating chronic musculoskeletal pain (Bradley and Alberts 1999). In fact, PSM incorporates important components of CBT with additional educational and behavioral strategies. Another important component of PSM programs is emotional coping and management (Lorig and Holman 2003). One advantage of PSM compared with CBT in the medical setting is that it may be effectively administered by varying levels of trained individuals, including lay personnel (Cohen et al. 1986; Kroenke et al. 2009a).

**Other psychological interventions.** Other reviews of psychological interventions for pain have shown a similar predominance of CBT trials (Morley et al. 2013). A meta-analysis of 27 RCTs of psychological interventions for treating arthritis found that CBT was used in 23 trials, stress management in 5, and biofeedback, emotional disclosure, and hypnosis in 1 trial each (several trials used more than one intervention) (Dixon et al. 2007). The reduction in pain was statistically significant but clinically rather small (pooled effect size: 0.18). Three systematic reviews of psychological treatments for somatic syndromes (many of which are manifested predominantly by pain) have also been heavily weighted with CBT studies (Allen et al. 2002; Henningsen et al. 2007; Raine et al. 2002). A large trial (N=1,337 patients) of telephone-based, nurse-administered problem-solving therapy (which is one of the evidence-based psychotherapies for depression) proved the therapy beneficial in primary care patients with chronic pain (Ahles et al. 2006), although further research is needed before one could recommend this over CBT or PSM programs.

Exercise

Exercise has been extensively studied in chronic pain patients and has been demonstrated to be an effective adjunctive treatment for several types of chronic pain disorders. Evidence regarding its effectiveness is discussed in more detail in the “Fibromyalgia” and “Osteoarthritis” sections. Six general issues relevant to initiating and maintaining an exercise program for chronic pain are summarized in Table 54-4.

**TABLE 54-4. Key principles for initiating and maintaining exercise for chronic pain**

Principle	Comments
-----------	----------

<b>Principle</b>	<b>Comments</b>
Type of exercise	Aerobic exercise is particularly important for some types of chronic pain (e.g., fibromyalgia), whereas strengthening and flexibility exercises may be helpful in others (back pain, osteoarthritis).
Catastrophizing as a barrier	Fear that movement or activity will worsen pain is common. Emphasizing that gradual activity will not cause further harm but instead can be beneficial is essential to activation and rehabilitation.
Stage of change	For patients in precontemplation phase, motivating them to initiate exercise is the challenge. For many others who begin an exercise program, getting them to maintain regular exercise for more than a few months is the critical issue. This is analogous to weight loss, smoking cessation, and other lifestyle or behavioral changes.
Graduated program	Patients should not try to do too much initially. Instead, they should begin slowly and increase the amount of exercise gradually over a matter of weeks to months.
Structured vs. home based	The benefits of structured exercise programs demonstrated in some research studies may have a “voltage drop” when patients are instructed to begin an exercise program on their own. Exercise conducted in clinical settings (e.g., physical therapy, rehabilitation programs) or community settings (e.g., YMCA, fitness centers) may be reinforced by motivation, group participation, expert leadership, guidance, and/or an externally imposed regular schedule.
Monotherapy vs. bundled	Many studies of exercise have included other components, such as education about the particular pain disorder, self-management techniques, relaxation, and other cognitive-behavioral strategies. Certainly, exercise coupled with one or more of these is ideal.

## Combination Therapy

Over time, the treatment of chronic pain often includes stepwise addition to a patient's regimen (and deletion if a therapy shows no benefit) of medications from several classes ([Black and Sang 2005](#); [Gallagher 2005](#)). In addition to medications given to produce analgesia, pain management may include medications to treat the side effects of the analgesics, such as laxatives or stool softeners for patients receiving opioids, gastroprotective medications for those receiving NSAIDs, and psychostimulants to combat excessive somnolence.

Very few studies have tested combinations of treatments to determine their additive value, if any, compared with monotherapy. Only limited data suggest that the combination of acetaminophen with NSAIDs has additive pain-relieving effects ([Schug 2005](#)). The largest trial (892 community-derived subjects) found greater pain relief with the combination of acetaminophen and ibuprofen than with either drug alone ([Doherty et al. 2011](#)). More data show a beneficial effect in combining acetaminophen with opioids, including codeine, tramadol, and morphine. Indeed, one of the more common fixed combinations in a single pill has been the coupling of an opioid, such as codeine, tramadol, oxycodone, or hydrocodone, with a nonopioid analgesic such as acetaminophen or aspirin. One important consideration in using fixed-dose combinations is that the maximum daily dosage of one component may restrict flexibility in optimizing the dosage of the other component. For example, when oxycodone 5 mg is combined with acetaminophen 500 mg, the maximum number of tablets that can be administered is eight in a 24-hour period (i.e., 4,000 mg of acetaminophen). If this is insufficient to manage the patient's pain, the opioid and nonopioid should be given as separate medications to allow further upward titration of the opioid.

Head-to-head clinical trials comparing different analgesics for chronic pain, separately or in combination, are rare. In addition to the acetaminophen-ibuprofen trial ([Doherty et al. 2011](#)), a second example is a small (57 subjects enrolled; 41 trial completers) randomized, double-blind crossover trial in patients with neuropathic pain, which showed that gabapentin and morphine combined achieved better analgesia at lower doses of each drug than either as a single agent ([Gilron et al. 2005](#)). On the other hand, the gabapentin-morphine combination resulted in a higher frequency of constipation than gabapentin alone and a higher frequency of dry mouth than morphine alone. A third small crossover trial (56 subjects enrolled; 45 trial completers) found the combination of gabapentin and nortriptyline to be superior to either drug alone for neuropathic pain ([Gilron et al. 2009](#)).

The common decision in clinical practice when optimal pain relief has not been achieved is whether to switch to a new treatment or to add it to what is currently being provided. Given the paucity of combination drug trials, this decision is currently guided by practical considerations. Switching to another monotherapy is often less costly than combining two or more treatments and often is done when a patient has had only a minimal response to and/or poor tolerance of the initial treatment. On the other hand, adding a second treatment may be favored when there has been at least a partial response to the first therapy or when the second treatment has a different mechanism of action that may complement the original treatment. Factors influencing combination therapy decisions include not only added efficacy but also costs, side effects, adherence, and patient preferences. Sometimes, the secondary effects of a drug may influence the decision to use it in a particular patient. For example, the side effect of sedation that occurs with certain medications (e.g., gabapentin or pregabalin) may be troublesome in one patient, whereas in another it may be useful to treat comorbid insomnia, particularly if taken at bedtime.

Likewise, the antidepressant effects of a particular adjunctive pain medication (e.g., an SNRI such as duloxetine) may reduce both pain and mood disturbances in the patient with diabetic neuropathic pain and comorbid major depression. TCAs could serve the same purpose, although higher dosages of TCAs are typically required for antidepressant action than for analgesic action, in which case the side effects of higher-dose TCAs, especially their cardiovascular effects, must be considered as well.

---

## Selected Pain Disorders

---

### Neuropathic Pain

[Chou et al. \(2007a\)](#) summarized several key points regarding the prevalence, etiology, and classification of neuropathic pain:

Neuropathic pain (NP) is often classified by etiology or by the presumed site of neurologic involvement (central or peripheral). More complex classification systems based on symptoms, signs, anatomical distribution, or hypotheses regarding etiologies have been proposed, but it is not clear if such classifications are accurate or reproducible. NP is characterized by continuous or intermittent spontaneous pain, typically characterized by patients as burning, aching, or shooting. Up to 3% of the general population reports NP at some time. NP is most commonly associated with painful diabetic neuropathy, postherpetic neuralgia (PHN), or lumbar nerve root compression. Diabetic neuropathy occurs in approximately 10% of persons with diabetes. The most common form of diabetic peripheral neuropathy is a distal symmetric polyneuropathy, typically manifested by symptoms beginning in the feet. PHN is defined as pain persisting or recurring at the site of acute herpes zoster 3 or more months after the acute episode. It occurs in up to 25% of patients following an episode of shingles. Symptomatic spinal stenosis and lumbar disc herniation with nerve root compression occur in approximately 3% and 4% of patients with low back pain, respectively. Other causes of NP include cancer-related pain, spinal cord injury, poststroke pain, HIV-associated neuropathy, and phantom limb pain. Uncommon but potentially debilitating NP conditions include trigeminal neuralgia (incidence 4/100,000 population). In the U.S., health care and disability-related costs associated with NP are estimated at almost \$40 billion annually. ([Chou et al. 2007a](#), p. 6)

A meta-analysis of 229 RCTs evaluating pharmacotherapy for neuropathic pain ([Finnerup et al. 2015](#)) showed generally modest effects on pain. One hundred twenty-seven (55%) of the 229 trials involved patients with diabetic painful polyneuropathy or postherpetic neuralgia. Pooled NNTs were 6.4 for SNRIs, mainly including duloxetine (7 of 9 studies positive) and venlafaxine (2 of 5 studies positive); 7.7 for pregabalin; 7.2 for gabapentin; and 10.6 for capsaicin high-concentration patches. NNTs were lower for TCAs, opioids, tramadol, and botulinum toxin A and were undetermined for lidocaine patches. Tolerability and safety were higher for topical drugs, and costs were lower for TCAs and tramadol. These findings led to the following:

1. A strong recommendation for TCAs, SNRIs, pregabalin, and gabapentin as *first-line* treatment;
2. A weak recommendation for lidocaine patches, capsaicin high-concentration patches, and tramadol as *second-line*; and
3. A weak recommendation for opioids and botulinum toxin A as *third-line*.

The recommendations from this comprehensive meta-analysis are generally consistent with previous guidelines from the Agency for Healthcare Research and Quality ([Chou et al.](#)

2007a), the European Federation of Neurological Sciences ([Attal et al. 2006](#)), the International Association for the Study of Pain (IASP) ([Dworkin et al. 2007](#)), and several other specialty organizations ([Bril et al. 2011](#)). They also concluded that diabetic and nondiabetic painful polyneuropathies are similar in symptomatology and response to treatment. The only exceptions noted were that HIV- and chemotherapy-induced neuropathy may be more refractory to treatment. The principal opioids studied have been oxycodone and tramadol, both of which have proven superior to placebo. Trials of topical capsaicin have provided discrepant results. The antiarrhythmic drug mexiletine, the *N*-methyl-D-aspartate antagonist memantine, and topical capsaicin have not shown convincing efficacy.

The IASP also noted that “Although few clinical trials have been conducted, no medications have demonstrated efficacy in patients with lumbosacral radiculopathy, which is probably the most common type of neuropathic pain” ([Dworkin et al. 2007](#), p. 237). Indeed, an RCT evaluating nortriptyline, morphine, and their combination in patients with chronic lumbar root pain found no greater efficacy with the combination than with either medication alone or placebo ([Khoromi et al. 2007](#)). Also, neuropathy related to HIV and cancer chemotherapy may be more refractory to treatment than other types of neuropathic pain. The IASP also noted that little is known regarding the treatment response of those with mild to moderate neuropathic pain because most trials have enrolled patients with more severe neuropathic pain, and long-term effectiveness is unknown because most RCTs have been of less than 3 months’ duration. The IASP also favored secondary-amine TCAs (nortriptyline and desipramine) over tertiary-amine TCAs (amitriptyline and imipramine) because of their comparable analgesia ([Max et al. 1992](#); [Rowbotham et al. 2005](#); [Watson et al. 1998](#)) and fewer side effects. Finally, the IASP concluded that the magnitude of pain reduction associated with opioid analgesics is at least as great as that obtained with other treatments for neuropathic pain.

Duloxetine, pregabalin, and gabapentin are the three FDA-approved drugs with the greatest amount of trial evidence and appear to have similar efficacy for diabetic neuropathic pain ([Quilici et al. 2009](#)). The most common adverse events for gabapentin and pregabalin include dizziness, somnolence, and weight gain, and nausea can be a perplexing side effect of SNRIs. Sometimes, a drug may be preferentially chosen because of comorbid conditions (e.g., gabapentin or pregabalin for the patient with neuropathic pain and insomnia, or duloxetine when neuropathic pain is accompanied by major depression). Switching or adding medications will frequently be necessary, because no more than 40%–60% of patients obtain partial relief from a single agent ([Dworkin et al. 2007](#)).

## Fibromyalgia

### Mechanisms and Evaluation

Fibromyalgia is one of the most common musculoskeletal disorders seen in rheumatology practice as well as primary care. It is often classified among the functional somatic syndromes (FSSs), which include irritable bowel syndrome, chronic fatigue syndrome, temporomandibular joint disorder, interstitial cystitis, and other symptom-based conditions manifested by a cluster of symptoms for which the pathophysiological mechanism is not well understood ([Aaron and Buchwald 2001](#)). Patients with one FSS often have one or more other FSSs as well as psychological comorbidity, including depression and anxiety, and a history of abuse during childhood or as adults. However, it does not appear that FSSs are entirely explained by psychological factors ([Henningesen et](#)

al. 2003), and emerging research also shows biological factors that may be causative or contributory.

The American College of Rheumatology core diagnostic criteria for fibromyalgia depend entirely on clinical history and exam and do not require any laboratory or radiological testing (Wolfe et al. 2010). Although tender points on physical examination were originally required, the revised diagnostic criteria now require only the following:

1. Generalized pain that is both widespread (i.e., on both the right and left sides of the body, upper and lower halves, and axial as well as proximal arms and legs) and chronic (lasting  $\geq 3$  months)
2. Somatic symptoms of which 3 cardinal symptoms are fatigue, unrefreshing sleep, and cognitive symptoms (sometimes called “fibro fog”) but can also include high numbers of other somatic symptoms

The other diagnostically useful finding is that unlike patients with arthritic conditions (e.g., osteoarthritis, rheumatoid arthritis, systemic lupus), who mainly suffer from arthralgias (pain and tenderness over the joints or periarticular regions), patients with fibromyalgia experience myalgias (pain and tender points in nonarticular regions). In fact, research shows that fibromyalgia patients feel tenderness wherever pressure is applied, including areas previously considered to be “control points” (Clauw 2007). The tenderness simply reflects the fibromyalgia patient’s tendency toward allodynia (experiencing pain from stimuli that would normally be nonpainful) or hyperalgesia (experiencing more severe pain from stimuli that would normally be only mildly painful). Given that the symptoms seem to arise from disturbances in the central processing of pain and that tender points are a relatively nonspecific finding, some have advocated calling the condition *chronic widespread pain* (Lee et al. 2014).

The primary problem in fibromyalgia appears to be not that there is too much input coming from the pressure nociceptors peripherally but rather that there is inadequate filtering of that activity, perhaps because of decreased activity of descending antinociceptive pathways. In fact, multiple mechanisms seem to be operative in fibromyalgia (Abeles et al. 2007). Two key mechanisms are as follows:

1. Functional imaging studies in fibromyalgia patients have shown increased blood flow to pain-relevant areas of the brain at lower thresholds of nociceptive input.
2. There appears to be dysregulation of descending inhibitory pain pathways. Thus, the pain “amplifier” is turned up, and the “mute” button is turned down in fibromyalgia patients. Collectively, this concept is known as *central sensitization* (Bourke et al. 2015).

Not only is fibromyalgia accompanied by psychiatric comorbidity, but it also can coexist with other rheumatological disorders. For example, as many as one-quarter of patients with rheumatoid arthritis and other systemic arthritides may also have fibromyalgia. Thus, if an individual with arthritis or another musculoskeletal disorder also has chronic widespread pain, therapies effective for fibromyalgia should be added to the treatment regimen. Also, communication with the patient, including explanations about central sensitization and abnormal pain processing, may be helpful. Despite assumptions that being “labeled” with fibromyalgia may adversely affect patients, it has been shown that patients have had significant improvement in health satisfaction and symptoms after having received this diagnosis (K.P. White et al. 2002).

## Pharmacotherapy

A comparison of fibromyalgia guidelines from three different countries (Table 54-5) reveals that the most evidence-based medications are TCAs, SNRIs (duloxetine, milnacipran),  $\alpha_2\delta$ -ligand anticonvulsants (pregabalin, gabapentin), and tramadol (Ablin et al. 2013). The strongest evidence is for the three drugs that have received FDA approval for fibromyalgia: pregabalin, duloxetine, and milnacipran. Although several trials (Bennett et al. 2003; Biasi et al. 1998; Russell et al. 2000) have shown the effectiveness of tramadol in fibromyalgia, the few studies of stronger opioids have not established their efficacy, and adverse effects appear to outweigh benefits (Goldenberg et al. 2016). Also, the few studies of NSAIDs in fibromyalgia have also had negative results, suggesting that a class of drugs considered first-line treatment for arthritis and other musculoskeletal disorders may not be effective in treating fibromyalgia.

**TABLE 54-5. Evidence-based fibromyalgia treatments from three national guidelines**

	Canada	Israel	Germany
Treatment	Strength of recommendation <sup>a</sup>		
<b>Pharmacotherapy</b>			
TCA (e.g., amitriptyline)	A	A	B
SNRI (duloxetine, milnacipran)	A	A	B/C
α <sub>2</sub> δ ligands (pregabalin, gabapentin)	A	A	C
Tramadol	C	B	—
SSRI	A	—	C
<b>Nonpharmacological therapies</b>			
Cognitive-behavioral therapy	A	A	A
Exercise (aerobic)	A	A	A
Balneotherapy (spas; hydrotherapy)	—	C	B

*Note.* SNRI=serotonin-norepinephrine reuptake inhibitor; SSRI=selective serotonin reuptake inhibitor; TCA=tricyclic antidepressant; —=not applicable.

<sup>a</sup>A=should be offered to most patients; B=may be offered to a majority of patients but may not be offered to a substantial minority; C=can be offered to a minority of patients.

*Source.* Adapted from Ablin et al. 2013.

A meta-analysis of four trials found that cyclobenzaprine (10–40 mg/day) was also superior to placebo (Arnold et al. 2000). Although classified as a muscle relaxant, cyclobenzaprine has a chemical structure closely related to that of the TCAs, which may partly account for its effectiveness in fibromyalgia.

In the Phase III trials that led to FDA approval, pregabalin dosages were 300–450 mg/day (divided into twice-daily doses), duloxetine dosages were 60–120 mg once a day,

and milnacipran dosages were 100–200 mg once a day. In all trials, the difference in efficacy between the highest and lowest dosages of each drug was small to minimal, whereas side-effect rates increased somewhat at higher dosages. Thus, the majority of fibromyalgia patients who respond to these drugs will do so with 300 mg of pregabalin, 60 mg of duloxetine, or 100 mg of milnacipran per day. The most bothersome side effect of duloxetine and of milnacipran (as well as venlafaxine) is nausea, which may be lessened by starting therapy at lower dosages (e.g., duloxetine 30 mg/day or venlafaxine 37.5 mg/day) for the first 1–2 weeks and by taking the drug with food. The most bothersome side effects with pregabalin and gabapentin are somnolence (which often improves with treatment and may be reduced by using low initial doses and having the patient take the only dose or the highest dose at bedtime), dizziness, and weight gain.

## Nonpharmacological Treatment

More than with most other pain disorders, nonpharmacological treatment for fibromyalgia is especially important, and few patients should be treated with medication only. Several systematic reviews have shown that the three treatments with the most evidence of efficacy are exercise (particularly aerobic exercise), education about fibromyalgia (either individually or in groups), and CBT ([Goldenberg et al. 2004](#); [Henningesen et al. 2007](#); [Sim and Adams 2002](#); [van Koulil et al. 2007](#)). Similarly, guidelines emphasize CBT and exercise ([Ablin et al. 2013](#)). A systematic review of 34 RCTs (involving 2,276 subjects) evaluated exercise in fibromyalgia and found that aerobic-only exercise had moderate positive effects on global well-being (effect size, 0.49), physical function (effect size, 0.66), and pain (effect size, 0.65) ([Busch et al. 2007](#)). Strength and flexibility exercises were underevaluated. A review of eight RCTs of balneotherapy (pool exercise) also showed beneficial results in fibromyalgia ([Gowans and deHueck 2007](#)), and this may be an alternative as an initial form of exercise for individuals with arthritis, to reduce weight bearing on arthritic joints, or for patients who fear exercise will exacerbate their pain. Seven RCTs of CBT (two of which also included exercise) involving a total of 595 patients showed benefits for CBT in five of the seven trials ([van Koulil et al. 2007](#)). Education about fibromyalgia has been studied in numerous trials, both individually and coupled with one or more other interventions, and appears to have a positive effect ([Goldenberg et al. 2004](#); [Sim and Adams 2002](#)). Education coupled with exercise seems a particularly valuable bundled intervention ([Burckhardt 2006](#); [Karjalainen et al. 2000](#); [Rooks et al. 2007](#)). Educational and self-management resources are readily available online from organizations like the National Fibromyalgia Association, the American College of Rheumatology, and the Arthritis Foundation. Finally, data are inconclusive regarding acupuncture, chiropractic therapy, massage therapy, yoga, trigger point injections, and other nonpharmacological or CAM treatments for fibromyalgia ([Ablin et al. 2013](#); [Goldenberg et al. 2004](#); [Henningesen et al. 2007](#); [Mayhew and Ernst 2007](#); [Sim and Adams 2002](#); [Tan et al. 2007](#)).

## Low Back Pain

A series of systematic reviews by Chou and colleagues ([Chou and Huffman 2007a, 2007b](#); [Chou et al. 2007b](#)) provides a comprehensive update on the evaluation and management of low back pain. The authors describe the burden of back pain:

Low back pain is the fifth most common reason for all physician office visits in the U.S. and the second most common symptomatic reason. Approximately one quarter of U.S. adults reported having low back pain lasting

at least one whole day in the past 3 months, and 7.6% reported at least one episode of severe acute low back pain within a 1-year period. Low back pain is also very costly: Total incremental direct health care costs attributable to low back pain in the U.S. were estimated at \$26.3 billion in 1998. In addition, indirect costs related to days lost from work are substantial, with approximately 2% of the U.S. work force compensated for back injuries each year. (Chou et al. 2007b, p. 478)

The authors go on to describe several other key points relevant to the clinical epidemiology of low back pain. Most low back pain (85%) is nonspecific—that is, it cannot be attributed to a specific disease or spinal abnormality. Classification schemes frequently conflict with one another, and there is little evidence that labeling patients by using specific anatomical diagnoses improves outcomes. In a primary care setting, low back pain is only occasionally caused by a specific serious disorder, such as cancer (0.7% of cases), compression fracture (4%), or spinal infection (0.01%). The estimated prevalence of ankylosing spondylitis in primary care patients ranges from 0.3% to 5%. Spinal stenosis and symptomatic herniated disc are present in about 3% and 4% of patients, respectively. The cauda equina syndrome, due to massive midline disc herniation, is very rare (occurring in 0.04% of patients with low back pain). Urinary retention is 90% sensitive, and the probability of the cauda equina syndrome in back pain patients without urinary retention is approximately 1 in 10,000. The probability of cancer in patients presenting with back pain increases from approximately 0.7% to 9% in patients with a history of cancer (not including nonmelanoma skin cancer). In patients with any one of three other risk factors (unexplained weight loss, failure to improve after 1 month, and age greater than 50 years), the likelihood of cancer only increases to approximately 1.2%.

Table 54-6 outlines some key recommendations with respect to the evaluation and management of low back pain. In the absence of red flags, a conservative approach for at least 4 weeks is usually warranted, even if sciatica is present. Magnetic resonance imaging is the preferred imaging procedure but can be reserved for the minority of patients with red flags or persistent symptoms, especially neurological findings. The two most common indications for surgery are herniated disc with persistent symptoms (especially radiculopathy) and spinal stenosis, which together account for less than 10% of cases of chronic back pain. Trial data suggest that surgery may be only marginally beneficial for pain due to a herniated disc but more helpful for spinal stenosis (Weinstein et al. 2006, 2008). Psychological factors are stronger predictors of low back pain treatment outcomes than either physical examination findings or the severity or duration of pain. Psychosocial factors that may predict poorer low back pain outcomes include presence of depression, passive coping strategies, job dissatisfaction, higher disability levels, disputed compensation claims, and somatization.

---

**TABLE 54-6. Key aspects of evaluation and management of low back pain**

---

Most back pain (>70%–80%) improves in the first 2–6 weeks. Thus, a 4-week wait (i.e., a conservative approach) is warranted (even with sciatica) in the absence of red flags.

Red flags that may prompt earlier diagnostic testing or referral include the following:

- Cancer: history of cancer (strong predictor) or unexplained weight loss, failure to improve after 4 weeks, and age greater than 50 years (all weaker predictors)

---

*Note.* ESR=erythrocyte sedimentation rate; MRI=magnetic resonance imaging; NSAIDs=nonsteroidal anti-inflammatory drugs; TCAs=tricyclic antidepressants.

- Infection (vertebral): fever, intravenous drug use, recent infection (none well studied)
- Compression fracture: older age, osteoporosis, steroid use
- Cauda equina syndrome rare (0.04%); urinary retention 90% sensitive.

Physical examination focuses on a few cardinal neurological parts of the lower-body exam:

- Straight-leg raising (SLR) in which the hip is flexed while the knee remains extended. Ipsilateral-positive SLR is 91% sensitive but only 26% specific for radiculopathy, whereas a crossed-positive SLR (i.e., sciatica in the other leg) is only 29% sensitive but 88% specific.
- Lower-extremity motor and sensory exam:
  - Knee strength and reflexes (L4 nerve root); screen with squat and rise
  - Great toe and foot dorsiflexion strength (L5 nerve root); screen with heel walking
  - Foot plantar-flexion and ankle reflexes (S1 nerve root); screen with walking on toes

Diagnostic tests are needed in only a minority of cases (with red flags or persistent neurological signs).

- MRI is the preferred imaging study (less radiation and better visualization of soft tissue, vertebral marrow, and the spinal canal).
- With some weaker red flags (e.g., age >50 years), plain films and ESR may be obtained first and MRI obtained only if these tests are abnormal or symptoms persist.

Psychological factors are a stronger predictor of chronicity and functional outcomes such as disability than physical exam findings or the severity or duration of pain.

Treatment: No treatment for back pain has good-quality (grade A) evidence of substantial benefit. The following have fair-quality (grade B) evidence of moderate benefit or small benefit but no significant harm, costs, or burdens:

- Pharmacotherapy: acetaminophen, NSAIDs, TCAs, tramadol/opiates, benzodiazepines
- Nonpharmacological: chiropractic, acupuncture, massage, yoga, exercise, progressive relaxation, cognitive-behavioral therapy, intensive interdisciplinary rehabilitation

---

*Note.* ESR=erythrocyte sedimentation rate; MRI=magnetic resonance imaging; NSAIDs=nonsteroidal anti-inflammatory drugs; TCAs=tricyclic antidepressants.

Medications are the most frequently recommended intervention for low back pain. The most commonly prescribed medications for low back pain are NSAIDs, skeletal muscle relaxants, and opioid analgesics ([Chou and Huffman 2007a](#)). Benzodiazepines, systemic corticosteroids, antidepressant medications, and antiepileptic drugs are also prescribed. Frequently used over-the-counter medications include acetaminophen, aspirin, and certain NSAIDs. No treatments for back pain have grade A evidence supporting their use—that is, good-quality evidence of substantial benefits. [Table 54-6](#) summarizes treatments with grade B evidence. For pharmacotherapy, this includes acetaminophen, NSAIDs, tramadol, and TCAs. For all medications, the evidence of beneficial effects on functional outcomes is limited. Skeletal muscle relaxants, which may be beneficial for acute back pain, do not have established efficacy for chronic pain. Although systematic reviews of opioids for various chronic pain conditions have shown moderate benefits, the evidence for opioids specifically for low back pain is sparse and inconclusive ([Martell et al. 2007](#)). A prospective study found that early prescription of opioids for acute occupational low back

injury was associated with an increased risk of work disability at 1 year, even after adjustment for severity of pain, function, and initial injury ([Franklin et al. 2008](#)). A systematic review of 25 trials involving 2,206 patients found no benefits for either continuous or intermittent traction in the treatment of low back pain ([Clarke et al. 2007](#)). There is also good evidence that systemic corticosteroids are ineffective for low back pain with or without sciatica. One systematic review identified only 7 trials evaluating medications for sciatica ([Vroomen et al. 2000](#)). Two small trials suggest that gabapentin may be useful in the subset of patients with radiculopathy.

Ten trials were included in two systematic reviews of antidepressants ([Salerno et al. 2002](#); [Staiger et al. 2003](#)). In all of the trials, the duration of therapy ranged from 4 to 8 weeks. Antidepressants were consistently superior to placebo for pain relief, whereas the benefits in terms of functional outcomes were uncertain. The pooled effect size for pain relief was moderate (0.41). Indirect comparisons suggested modest benefits with TCAs but not with paroxetine or trazodone. A recent review of six trials of duloxetine in patients with back pain showed an analgesic benefit ([Pergolizzi et al. 2013](#)).

## Osteoarthritis

Osteoarthritis is one of the most common musculoskeletal pain disorders (along with low back pain and fibromyalgia) in both primary care and specialty settings. It typically increases with age (particularly after age 50 years), with the majority of individuals older than 65 years having at least one joint affected by osteoarthritis. Common joints involve the distal and proximal interphalangeal (but not metacarpal) joints of the fingers, the base of the thumb, the knees, the hips, and the cervical and lumbar regions of the spine. The shoulder and elbow are rarely involved. The most common finding on physical examination is an increase in joint size secondary to osteophyte formation. Plain radiographs are typically the only diagnostic test required to confirm the diagnosis of osteoarthritis, which is manifested by loss of joint space and/or osteophyte formation.

In contrast to the case in rheumatoid arthritis and other inflammatory types of arthritis, the structural changes in osteoarthritis are not amenable to specific disease-modifying treatments. Thus, the focus of treatment in osteoarthritis is reduction of pain and preservation of function. Acetaminophen and NSAIDs, which are inexpensive and available without a prescription, are the mainstays of pharmacotherapy. A systematic review of 13 trials in patients with osteoarthritis of the knee found that both aerobic exercise and home-based quadriceps-strengthening exercise reduced pain (effect sizes, 0.52 and 0.39, respectively) and disability (effect sizes, 0.46 and 0.32) ([Roddy et al. 2005](#)). Benefits of aerobic and strengthening exercises in osteoarthritis patients were confirmed in a second systematic review ([Brosseau et al. 2003](#)). For advanced disease with progressive pain and functional impairment, total hip arthroplasty and knee arthroplasty are effective. In contrast, a systematic review of 23 studies found inconclusive evidence for the benefits of arthroscopic lavage and/or debridement in knee osteoarthritis ([Samson et al. 2007](#)). The lack of efficacy for lavage, with or without intra-articular corticosteroids, was confirmed in a meta-analysis of six trials involving 855 patients ([Avouac et al. 2010](#)). Glucosamine, chondroitin, and intra-articular hyaluronic acid have been the most popular CAM treatments for osteoarthritis, but multiple meta-analyses and systematic reviews ([Table 54-7](#)) found insufficient evidence to support the efficacy of either glucosamine or chondroitin. In contrast, hyaluronic acid seems to be effective in knee osteoarthritis, although it does require intra-articular administration. It also seems to be similar in

efficacy to continuous NSAID therapy (Bannuru et al. 2014) and intra-articular corticosteroids (Bannuru et al. 2009).

**TABLE 54-7. Glucosamine, chondroitin, and hyaluronic acid for osteoarthritis (OA) summary of systematic reviews**

Treatment	Study	Condition	Review type	Benefits	Strength of evidence	Comments
Glucosamine	Vlad et al. 2007	Knee or hip OA	Meta-analysis (15 trials, 2,825 patients)	Not known	Moderate	Glucosamine hydrochloride (three trials) did not have a significant effect (0.06), glucosamine sulfate (three trials) (0.44). However, large heterogeneity among studies made conclusions about effectiveness uncertain.
Glucosamine	Wu et al. 2013	Knee or hip OA	Meta-analysis (19 trials, 3,195 patients)	No	Moderate	Neither glucosamine hydrochloride nor glucosamine sulphate had a significant effect (0.03 and 0.22, respectively) in trial weeks or 12 weeks.

*Note.* GAIT=Glucosamine-Chondroitin Arthritis Intervention Trial.

<b>Treatment</b>	<b>Study</b>	<b>Condition</b>	<b>Review type</b>	<b>Benefits</b>	<b>Strength of evidence</b>	<b>Comments</b>
Chondroitin	<a href="#">Reichenbach et al. 2007</a>	Knee or hip OA	Meta-analysis (20 trials, 3,846 patients)	No	Moderate	Minimal effect on symptoms. Only the large high quality trials which accounted for 40% of patients.
Glucosamine and/or chondroitin	<a href="#">Distler and Anguelouch 2006</a>	Knee or hip OA	Network meta-analysis (10 trials, 3,803 patients)	No	Moderate	Review of prior network analysis of large clinical trials concluded that neither glucosamine nor chondroitin were effective for OA.
Glucosamine and/or chondroitin	<a href="#">Wandel et al. 2010</a>	Knee or hip OA	Review of prior reviews	No	Moderate	All trials of patients with knee OA comparing glucosamine vs. placebo, chondroitin vs. placebo, and 1 trial comparing glucosamine vs. chondroitin vs. placebo. No effect on either joint space narrowing

---

*Note.* GAIT=Glucosamine-Chondroitin Arthritis Intervention Trial.

Treatment	Study	Condition	Review type	Benefits	Strength of evidence	Comments
Glucosamine and/or chondroitin	<a href="#">Samson et al. 2007</a>	Knee OA	Systematic (21 trials)	Not known	Moderate	Evidence small to moderate. The GAIT study included 1,583 patients and showed no difference from placebo.
Hyaluronic acid (intra-articular)	<a href="#">Arrich et al. 2005</a>	Knee OA	Meta-analysis (22 trials)	No	Moderate	Small but clinically insignificant effect on pain. Confirmed in four high quality studies.
Hyaluronic acid (intra-articular)	<a href="#">Samson et al. 2007</a>	Knee OA	Systematic (42 trials)	Not known	Moderate	Generally no modes of benefit compared with placebo but unclear clinical significance.
Hyaluronic acid (intra-articular)	<a href="#">Bannuru et al. 2011</a>	Knee OA	Meta-analysis (54 trials, 7,545 patients)	Yes	Moderate	Small to moderate effect sizes for pain at week 4 (0.31), week 8 (0.46), and week 24 (0.21).
Hyaluronic acid (intra-articular)	<a href="#">Miller and Block 2013</a>	Knee OA	Meta-analysis (29 trials, 4,866 patients)	Yes	Moderate	Moderate effect sizes (0.43) for knee pain over 4 weeks.

*Note.* GAIT=Glucosamine–Chondroitin Arthritis Intervention Trial.

[Avouac et al. \(2007\)](#) conducted a meta-analysis of trials evaluating opioid therapy in osteoarthritis patients. Of the 18 placebo-controlled trials, 13 assessed pain intensity for 2,438 participants receiving opioids and 1,295 receiving placebo. Six studies evaluated

stronger opioids (oxycodone in 4 studies, fentanyl and morphine in 1 study each), and 7 studies examined weaker opioids (tramadol in 4 studies, tramadol-acetaminophen combination in 2 studies, and codeine in 1 study). The median trial duration was 12 weeks. The pooled effect size for pain intensity was moderate, at  $-0.79$  (95% CI= $-0.98$  to  $-0.59$ ). Sensitivity analysis showed no changes in the conclusions by type of opioid studied, type of scale used to assess pain, or methodological quality of the study. Physical function was assessed in 5 trials, with 1,429 participants receiving opioids (tramadol-acetaminophen in 2 studies; morphine, tramadol, and codeine in 1 study each) and 595 receiving placebo. The median trial duration was 4 weeks. The pooled effect size for physical function was small, at  $-0.31$  (95% CI= $-0.39$  to  $-0.24$ ). Again, sensitivity analyses did not change the conclusions. The average treatment discontinuation rate for toxicity was 25% in the opioid group (31% for strong opioids and 19% for weak opioids) versus 7% in the placebo group.

In contrast to the many trials of antidepressants for neuropathic pain, fibromyalgia, and chronic low back pain, few studies have investigated antidepressants for the treatment of osteoarthritic pain. One exception is duloxetine, for which three trials in osteoarthritis have shown efficacy for pain ([Pergolizzi et al. 2013](#)). However, other studies have shown that when depression co-occurs with arthritis, it can explain as much of the variance in pain intensity as objective severity of the arthritis ([Katon et al. 2007](#)). Also, RCTs have shown that treatment of depression in arthritis patients may reduce pain as well as depression ([Kroenke et al. 2009a](#); [E.H. Lin et al. 2003](#)). Thus, while antidepressants cannot currently be recommended as a first-line treatment in osteoarthritis patients without depression, screening for and co-managing depression may benefit patients in their pain outcomes.

## Headache

Although there are less common and/or more serious causes of headache, most individuals with chronic headache have either migraine headache or tension-type headache (TTH). Up to one-third of the general population report TTH, and 10% experience migraine headaches ([Robbins and Lipton 2010](#)). However, more patients with migraine headache present to physicians for care. Contrary to public perceptions, sinus disease, hypertension, and eye strain are not common causes of headache.

Migraine is easier to diagnose in the presence of aura, which most commonly include a visual prodrome such as blind spots (scotomas), zigzag patterns (fortification spectra), or flashing lights (scintilla). However, aura occur in less than 20% of patients with migraine attacks.

Diagnostic criteria can differentiate migraine headache from TTH ([Toward Optimized Practice 2012](#)). Migraine without aura is diagnosed if at least two of the following are present: 1) nausea during the attack, 2) light sensitivity during the attack; and 3) some of the attacks interfere with the patient's activities. TTH is diagnosed if headaches are not associated with nausea and at least two of the following are present: 1) bilateral headache, 2) nonpulsating pain, 3) mild to moderate intensity, and 4) headache is not worsened by activity.

Some individuals with migraine or TTH develop chronic daily headache (CDH), defined as a headache frequency of  $\geq 15$  days a month for longer than 3 months. A common reversible cause of CDH is medication overuse headache (MOH), which can develop when analgesics are taken for headaches more than 2-3 days per week. Whereas all analgesics have the potential for MOH, the risk appears to be the highest with opioids or combination analgesics containing butalbital or caffeine, intermediate with triptans, and lowest with

NSAIDS. MOH often manifests as a headache that is present upon awakening and that responds to analgesics with only transient relief. This in turn can lead to a vicious circle of increased analgesic use.

Neuroimaging has a low yield in the evaluation of headaches. Even among selected patients with headache seen in tertiary referral centers, less than 1%–2% have abnormal imaging findings that influence treatment ([Clarke et al. 2010](#); [Dumas et al. 1994](#)). Factors that may justify an imaging study are focal neurological signs or symptoms, onset of headache after age 40 years, and severe or worsening headaches that do not respond to appropriate therapy.

An initial stepped-care approach to pharmacotherapy for migraine and TTH is summarized in [Table 54–8](#). Because migraine headache is both more disabling and more prevalent among patients who seek care, the amount of clinical trial evidence available, as well as the number of medications that have been well studied, is greater than for TTH. Treatment of less common types of headache (e.g., cluster headache) or chronic refractory headache probably warrants referral to a neurologist or other clinician specializing in headache management.

**TABLE 54–8. Stepped-care pharmacotherapy for headache**

Medication	Migraine	Tension type
Acute (abortive)		
Step 1	NSAID	Acetaminophen or NSAID
Step 2	Triptan	
Step 3	Opioid	
Prophylactic (preventive)		
Step 1	Beta-blocker	Amitriptyline or nortriptyline
Step 2	Topiramate	
Step 3	Divalproex	

*Note.* NSAID=nonsteroidal anti-inflammatory drug.

## Algorithmic Approach to Treatment of Chronic Pain

This chapter has focused on the main classes of treatments for chronic pain, with a particular emphasis on pharmacotherapy. Five of the most common pain disorders have been discussed: neuropathic pain, fibromyalgia, low back pain, osteoarthritis, and headache. Based on our reviews within these parameters, an evidence-based stepped-care algorithm for treating pain is summarized in [Table 54–9](#), adapted from our previous review ([Kroenke et al. 2009b](#)) and tested (in an earlier version) in a clinical trial ([Kroenke et al. 2014](#)).

**TABLE 54–9. Evidence-based stepped-care analgesic algorithm by type of pain co**

Step	Medication	Dosing	Musculoskeletal <sup>a</sup>	Fibromyalgia	NeuropathicHe
<b>1</b>	<b>Simple analgesics</b>				
	Acetaminophen	650–1,000 mg every 6h (maximum of 3,000–4,000 mg/day, but only 2,000 mg/day if cirrhosis or $\geq 3$ alcoholic drinks/day)	+	+	+
	NSAIDs <sup>b,c</sup>				
	Naproxen	500 mg every 12h, or 500 mg in A.M. and then 250 bid (up to 1,000 mg/day)	+	+	+
	Ibuprofen	600 mg every 6h (maximum 2,400 mg/day)	+	+	+
	Salsalate	1,000 mg every 8h or 1,500 mg every 12h (up to 3,000 mg/day)	+	+	+

*Note.* bid=twice daily; hs=at bedtime; NSAID=nonsteroidal anti-inflammatory drug; q times daily; SNRI=serotonin-norepinephrine reuptake inhibitor; TCA=tricyclic antidepressant; tid=three times daily.

++=U.S. Food and Drug Administration approved and/or strong evidence from 1 randomized controlled trials. +=Moderate evidence;  $\pm$ =Mixed (inconclusive) evidence.

<sup>a</sup>Includes back pain, osteoarthritis, and other localized joint or musculoskeletal pain.

<sup>b</sup>This is not a list of all drugs in this class.

<sup>c</sup>Consider trials of at least two NSAIDs; over-the-counter=naproxen, ibuprofen, ketoprofen.

<sup>d</sup>Triptans used for acute migraine treatment; other drugs used for migraine prevention.

Step	Medication	Dosing	Musculoskeletal <sup>a</sup>	Fibromyalgia	NeuropathicHe
	Meloxicam	7.5–15 mg/day (up to 15 mg/day)	+	+	+
	Etodolac	300 mg every 8h or 500 mg every 12h (maximum 1,000 mg/day)	+	+	+
	Diclofenac	50 mg every 8h (maximum 150 mg/day)	+	+	+
	Sulindac	150–200 mg bid (maximum 400 mg/day)	+	+	+
<b>2</b>	<b>TCAs<sup>b</sup></b>				
	Amitriptyline	Start at 10–25 mg; titrate to 100 mg		+	+
	Nortriptyline	Start at 10–25 mg; titrate to 100 mg		+	+
<b>2</b>	<b>Muscle relaxants<sup>b</sup></b>				

*Note.* bid=twice daily; hs=at bedtime; NSAID=nonsteroidal anti-inflammatory drug; q times daily; SNRI=serotonin-norepinephrine reuptake inhibitor; TCA=tricyclic antidepressant; tid=three times daily.

++=U.S. Food and Drug Administration approved and/or strong evidence from 1 randomized controlled trials. +=Moderate evidence; ±=Mixed (inconclusive) evidence.

<sup>a</sup>Includes back pain, osteoarthritis, and other localized joint or musculoskeletal pain.

<sup>b</sup>This is not a list of all drugs in this class.

<sup>c</sup>Consider trials of at least two NSAIDs; over-the-counter=naproxen, ibuprofen, ketoprofen.

<sup>d</sup>Triptans used for acute migraine treatment; other drugs used for migraine prevention.

Step	Medication	Dosing	Musculoskeletal <sup>a</sup>	Fibromyalgia	NeuropathicHe
	Cyclobenzaprine	5-10 mg bid to tid (maximum 20-30 mg total daily dose)	+	±	
	Methocarbamol	Start at 500 mg qid; can increase to 1,000 mg qid	±	±	
	Tizanidine	Start at 2 mg tid; can increase to 6-8 mg tid			
<b>2</b>	<b>Gabapentoids</b>				
	Gabapentin	Start at 100 mg tid; titrate to 900-1,200 mg tid		±	++
	Pregabalin	Start at 75-100 mg bid; titrate to 450 mg/day total in bid doses		++	++
<b>2</b>	<b>SNRI antidepressants</b>				
	Venlafaxine	75 mg/day sustained release; titrate to 225 mg/day		±	±

*Note.* bid=twice daily; hs=at bedtime; NSAID=nonsteroidal anti-inflammatory drug; q times daily; SNRI=serotonin-norepinephrine reuptake inhibitor; TCA=tricyclic antidepressant; tid=three times daily.

++=U.S. Food and Drug Administration approved and/or strong evidence from 1 randomized controlled trials. +=Moderate evidence; ±=Mixed (inconclusive) evidence.

<sup>a</sup>Includes back pain, osteoarthritis, and other localized joint or musculoskeletal pain.

<sup>b</sup>This is not a list of all drugs in this class.

## Other Issues

### Treatment of Pain Comorbid With Depression or Anxiety

As mentioned earlier, there is substantial evidence for a pain-depression dyad and probably a pain-depression-anxiety triad (see “Psychiatric Comorbidity”). The comorbidity among these disorders ranges from 30% to 60%, and they have reciprocal adverse effects on quality of life, disability, health care use, and treatment response. In particular, the presence of pain negatively affects depression outcomes, while depression in turn makes pain treatments less effective. Anxiety may have a similar effect, although the research in this area is less substantial than for depression.

Several trials have shown that depression treatment also benefits patients on pain outcomes, although the effect size for pain is only about half that for depression (Greco et al. 2004; Kroenke et al. 2009a; E.H. Lin et al. 2003). Other trials have demonstrated the

effectiveness of simultaneous treatment of chronic pain and comorbid depression ([Kroenke et al. 2009a, 2010](#)). Several suggestions may be considered. First, pain should be asked about when treating depressed or anxious patients, particularly in those who are not achieving remission or optimal responses. Likewise, psychiatric screening should be considered in patients with persistent pain, possibly with brief measures that screen for both depression and anxiety ([Kroenke et al. 2009c](#)). Second, it may be that antidepressant selection is important when pain is a major problem. For some types of pain conditions, TCAs and SNRI antidepressants appear to be more effective than SSRI or other antidepressants, although head-to-head trials are still few. Third, adding CBT, PSM programs, or other nonpharmacological treatments proven effective for pain could be considered. Fourth, optimizing analgesic management in patients with depression and pain, rather than simply focusing on depression medications, may be important. Increasingly, we may need to consider pain and depression as dual diagnoses, where attention to both is necessary to optimize patients' outcomes.

## Placebo Effect

As with other symptom-based conditions (e.g., depression, anxiety, somatoform disorders), pain has a placebo response in the 30%–40% range or higher. This can make it challenging to separate the specific effects of a pain treatment—medication or nonpharmacological—from placebo or other nonspecific effects. A network meta-analysis of 149 trials in adults with osteoarthritis showed that the effect size for intra-articular or topical placebo was greater than that for oral placebo ([Bannuru et al. 2015](#)). In the model accounting for differential effects, intra-articular and topical therapies were superior to oral treatments in reducing pain. When these differential effects were ignored, oral NSAIDs were superior. At the same time, the role of placebo effects on pain outcomes can be useful in clinical practice, including patient expectancy for an analgesic outcome and the clinical benefits of a positive therapeutic relationship. Pain is the most frequent reason for seeking CAM care ([Astin 1998](#)). Although evidence for several CAM treatments may still be lacking, their placebo effects coupled with frustration among many allopathic physicians and patients in the context of chronic pain may account for the popularity of CAM treatments for pain.

Experimental work has also revealed some interesting physiological effects of placebo. A meta-analysis of 12 studies (1,183 participants) was conducted to examine the effects of placebo and an opioid antagonist, naloxone, on pain ([Sauro and Greenberg 2005](#)). Placebo administration was associated with a decrease in self-reported pain, and a hidden or blind injection of naloxone reversed placebo-induced analgesia. An experimental study in 20 healthy subjects found that the placebo and nocebo effects (i.e., the therapeutic and adverse effects, respectively, of inert substances or sham procedures) are associated with opposite responses of dopaminergic and endogenous opioid neurotransmission in a distributed network of regions throughout the brain ([Scott et al. 2008](#)). The results support other literature showing that the belief in and expectation of analgesia induce discrete physiological changes, leading to relief from pain, and this response may be mediated by endogenous opioids.

Clinical ways to take advantage of the placebo effects of an analgesic are summarized by [Klinger et al. \(2014\)](#):

- **Enhancing expectations**—examples include 1) emphasis on positive drug effects and avoidance of an overemphasis on side effects; 2) explaining the mechanism of drug

action; 3) personal interaction rather than only written materials; and 4) explaining the course of drug action while avoiding unrealistic promises.

- **Enhancing learning components**—examples include 1) focusing on sensory aspects of a pain medicine such as its color or size to distinguish it from other medicines the patient may be taking; 2) association of analgesic medication with positive internal states and positive external conditions; 3) combining analgesic intake with other pain-relieving techniques; and 4) time-contingent (scheduled) rather than pain-contingent (intermittent) use of analgesics.

## Assessment and Monitoring of Pain

Inadequate pain assessment has been identified as a key barrier to appropriate pain management. Important initiatives have aimed to increase awareness of pain as a clinical problem by promoting better pain assessment. The U.S. Department of Veterans Affairs (VA) campaign promoting “pain as the fifth vital sign” requires all VA facilities to assess patients using a numeric rating scale (NRS) of 0–10 for current pain, where 0 is “no pain,” 5 is “moderate pain,” and 10 is “worst pain possible.” Even more far-reaching, the [Joint Commission on Accreditation of Healthcare Organizations \(2000\)](#) pain assessment and management standards, implemented in 2001, require accredited health care facilities to assess all patients for pain in both inpatient and ambulatory care settings. Although Joint Commission standards do not mandate a specific method of pain assessment, many organizations have responded by adopting use of an NRS of pain as the “fifth vital sign” ([Dahl 2002](#)). However, this movement has not led to clear improvements in the quality or outcomes of chronic pain management, and studies have shown that the NRS may not be the optimal measure for assessing and monitoring chronic pain in clinical practice ([Krebs et al. 2007](#); [Mularski et al. 2006](#)). An important limitation of single-item pain measurement is that it provides an overly simplified picture of a complex subjective experience.

Consensus recommendations from the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) included four core chronic pain outcome domains for monitoring treatment response: pain intensity (i.e., severity), physical functioning (i.e., pain-specific disability), emotional functioning (largely depression), and patient-rated overall improvement ([Dworkin et al. 2008](#)). The first two domains are captured in the PEG pain scale, which has been validated and is based on three items from the Brief Pain Inventory (average Pain severity, interference with Enjoyment of life, and interference with General activities), shown in [Figure 54-1](#) ([Krebs et al. 2009, 2010](#)). For emotional functioning, a clinical or patient-rated assessment of depression is recommended. For overall improvement, the single-item Patient Global Impression of Change scale uses a seven-point rating scale with the options “very much improved,” “much improved,” “minimally improved,” “no change,” “minimally worse,” “much worse,” and “very much worse.”

**1. What number best describes your pain on average in the past week?**

0	1	2	3	4	5	6	7	8	9	10
No pain										Pain as bad as you can imagine

**2. What number best describes how, during the past week, pain has interfered with your general activity?**

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

**3. What number best describes how, during the past week, pain has interfered with your enjoyment of life?**

0	1	2	3	4	5	6	7	8	9	10
Does not interfere										Completely interferes

**FIGURE 54-1.** PEG three-item pain scale.

The PEG three-item pain scale—an ultrabrief measure for assessing and monitoring pain—is based on three items from the Brief Pain Inventory: average **P**ain severity, interference with **E**njoyment of life, and interference with **G**eneral activities.

## Gaps in Knowledge Base Regarding Treatment of Chronic Pain

There are several important gaps in our knowledge regarding treatment that in fact are probably not unique to chronic pain. First, there is a paucity of head-to-head trials, meaning that although we can draw conclusions about the effectiveness of a particular monotherapy compared with a placebo or minimal treatment, we have much less information about the comparative effectiveness of different treatments. Second, few trials have evaluated different strategies for choosing initial treatment, so that deciding between first-line and subsequent treatments is more a matter of expert consensus, clinician experience, and patient preferences. Third, evidence is sparse on the effectiveness of dual-medication or other combination therapy versus monotherapy or sequential treatment, even though patients are frequently prescribed more than one medication or treatment. Fourth, most treatment trials have been short-term, so evidence of benefits sustained beyond 4–12 weeks is often lacking; this is a critical gap given the fact that our focus is on the management of chronic pain.

Despite these gaps, substantial evidence has accumulated over the past several decades about what works and what does not work for treating chronic pain. Avoiding ineffective treatments and maximizing the use of treatments proven beneficial in clinical trials are

likely to produce better outcomes than have often been experienced by clinicians and patients in the management of chronic pain.

## CHAPTER 55

# Treatment of Child and Adolescent Disorders

Karen Dineen Wagner, M.D., Ph.D.

Steven R. Pliszka, M.D.

This chapter focuses on the use of psychopharmacology for treating psychiatric disorders in children and adolescents. It is important for clinicians to be aware of the evidence base for the use of psychotropic medications in children and adolescents. In this chapter, data from the literature, with a focus on controlled studies, are presented. On the basis of these findings, clinical recommendations regarding pharmacotherapy for childhood psychiatric disorders are offered. The appendix and tables at the end of this chapter contain specific information about dosages, monitoring, and adverse effects of psychotropic medications in children.

---

# Psychotropic Medication for Children and Adolescents

---

## Evaluation

Prior to the initiation of psychotropic medication for children and adolescents, a comprehensive evaluation is necessary to ensure the accuracy of the diagnosis. A thorough history and careful attention to the clinical presentation are central components of the evaluation. The clinician should interview the child and parents separately so that both may have the opportunity to freely express their concerns. Extended-family members, school personnel, and school records are other potential sources of information.

Clinicians must be skilled at differential diagnosis of childhood disorders, given that there is a significant overlap of symptoms among these disorders. Knowledge of commonly occurring comorbid disorders is also necessary. Medical conditions should be considered within the differential diagnosis and adequately assessed.

Disorder-specific rating scales at baseline and during the course of treatment may be useful in assisting with the measurement of clinical outcome.

## Clinical Issues Affecting Response to Pharmacotherapy

Whenever a child fails to respond to initial pharmacotherapy, several clinical issues should be

addressed before initiating alternative or adjunctive medication.

## **Diagnostic Accuracy**

The diagnosis should be reassessed. Often there is symptomatic overlap among disorders that may lead to misdiagnosis. For example, symptoms of excessive energy and distractibility are common features of both attention-deficit/hyperactivity disorder (ADHD) and bipolar disorder.

## **Comorbid Disorders**

Unrecognized comorbid disorders may adversely affect treatment outcome. As an example, comorbid ADHD may lower response rates in the treatment of bipolar disorder ([Pavuluri et al. 2006](#)).

## **Psychosocial Factors**

Child abuse, domestic violence, family conflict, parental psychopathology, and bullying by peers may lead to symptoms that mimic or exacerbate a preexisting psychiatric disorder.

## **Medication Compliance**

Some children and adolescents are reluctant to take medication because of such reasons as denial of illness, perceived stigma, and side effects. For increased medication compliance, the child or adolescent, as well as the parents, must understand the youth's disorder, course of illness, and goals of treatment. It is important for parents to participate in monitoring their child's medication compliance.

## Nonpharmacological Treatment

Psychotherapy may be beneficial, either alone or in conjunction with medication. Specific psychotherapies have been found to be effective in the treatment of some childhood disorders. For example, cognitive-behavioral therapy (CBT) and interpersonal therapy have demonstrated efficacy in the treatment of adolescents with depression ([Zhou et al. 2015](#)). Similarly, CBT is commonly used for the treatment of childhood anxiety disorders ([Roblek and Piacentini 2005](#)). Behavior therapy has led to improvement in symptoms of ADHD for children ([Pelham et al. 1998](#)). Adjunctive psychoeducation with medication treatment has shown benefit in the treatment of children with bipolar disorder ([Fristad et al. 2003](#)). Social skills training can be a useful component of treatment in autism spectrum disorder ([Krasny et al. 2003](#)).

## Informed Consent

Informed consent is necessary prior to prescribing psychotropic medication to any patient, but it is particularly important in pediatric psychopharmacology because few medications have been approved by the U.S. Food and Drug Administration (FDA) for young populations. There are five recommended components of informed consent for prescribing psychotropic medications to children and adolescents ([Popper 1987](#)). The child's parent(s) and the child or adolescent should be provided with the following information:

1. The purpose (benefits) of the treatment
2. A description of the treatment process

3. An explanation of the risks of the treatment, including risks that would ordinarily be described by the psychiatrist and risks that would be relevant to making the decision
4. A statement of alternative treatments, including nontreatment
5. A statement that there may be unknown risks associated with these medications (this is particularly essential for children due to the paucity of information on the potential long-term effects of psychotropic medications)

## Evidence Base

It is important for clinicians to be aware of the evidence base for medication treatment of each childhood psychiatric disorder. Clinical treatment guidelines generally rely on the strength of the available data in determining first-line agents. In most cases, clinicians should select a medication within the group of first-line agents when initiating medication treatment with a child. Additional factors that will dictate medication choice are prior medication history, medical history, side-effect profile of the drug, and adolescent and parent preferences.

---

## Major Depressive Disorder

---

The lifetime prevalence of major depression or dysthymia in adolescents is 11.7% ([Merikangas et al. 2010](#)). DSM-5 ([American Psychiatric Association 2013](#)) criteria are used to establish a diagnosis of major depression in children and adolescents. The mean length of an episode of major

depression in youth ranges from 8 to 13 months, and relapse rates range from 30% to 70% ([Birmaher et al. 2002](#)). There is increasing evidence for the continuity of depression from youth into adulthood ([Melvin et al. 2013](#)).

## Selective Serotonin Reuptake Inhibitors

For the acute and maintenance treatment of major depression in children and adolescents, the FDA has approved two selective serotonin reuptake inhibitor (SSRI) medications: fluoxetine for patients ages 8 years and older and escitalopram for patients ages 12 years and older. Other SSRIs that have been studied in controlled trials for children and adolescents with major depression include citalopram, sertraline, and paroxetine.

### Fluoxetine

There have been three positive controlled medication trials of fluoxetine in the treatment of major depression in children and adolescents. In the first study, 96 child and adolescent outpatients (ages 8–17 years) with major depression were randomly assigned to fluoxetine 20 mg/day or placebo for an 8-week trial ([Emslie et al. 1997](#)). The fluoxetine group, with 27 youths (56%) much or very much improved, showed statistically significantly greater improvement in Clinical Global Impression (CGI) Scale scores than the placebo group, with 16 youths (33%) much or very much improved. Medication side effects leading to discontinuation in the study were manic symptoms in three patients and severe rash in one patient.

In a double-blind, placebo-controlled multicenter study of fluoxetine, 219 child and adolescent outpatients (ages 8–17 years) with major depression were randomly assigned to fluoxetine 20 mg/day or placebo for an 8-week trial ([Emslie et al. 2002](#)). Improvement in depression was statistically significantly greater for the fluoxetine group, as assessed by means of the Children's Depression Rating Scale—Revised (CDRS-R), than for the placebo group. Fifty-two percent of patients treated with fluoxetine were rated as much or very much improved, compared with 37% of patients treated with placebo. Headache was the only side effect that was reported more frequently in the group treated with fluoxetine than in the group treated with placebo.

In a multicenter trial of 439 adolescent outpatients with a diagnosis of major depression ([March et al. 2004](#)), patients were randomly assigned to 12 weeks of fluoxetine (10–40 mg/day), fluoxetine (10–40 mg/day) with CBT, CBT alone, or placebo. Compared with placebo, the combination of fluoxetine with CBT was significantly superior, according to changes in CDRS-R scores. Combination treatment with fluoxetine and CBT was significantly superior to treatment with fluoxetine alone or CBT alone. Fluoxetine monotherapy was superior to CBT. Response rates (defined as CGI ratings of much or very much improved), were 71% for fluoxetine–CBT combination therapy, 61% for fluoxetine, 43% for CBT, and 35% for placebo.

## **Escitalopram**

There have been two controlled trials of escitalopram in the treatment of youth with depression, one positive and one negative. The efficacy of escitalopram in adolescents was demonstrated in a double-blind, placebo-controlled

multicenter trial of 157 adolescents with major depression ([Emslie et al. 2009](#)). Patients were randomly assigned to escitalopram (dosage range=10-20 mg/day) or placebo for an 8-week trial. The group treated with escitalopram showed statistically significantly greater improvement in depression (CDRS-R scores) than the placebo group. Sixty-four percent of escitalopram-treated patients were much or very much improved, compared with 53% of placebo-treated patients. In a study that included 264 children and adolescents with major depression ([Wagner et al. 2006a](#)), there was no significant improvement on CDRS-R scores at endpoint between escitalopram and placebo. The most common adverse events with escitalopram were headache, abdominal pain, nausea, insomnia, and menstrual cramps.

## Citalopram

There have been two controlled trials of citalopram in the treatment of depression in youth, one with positive and one with negative results. The efficacy of citalopram was demonstrated in a double-blind, placebo-controlled multicenter trial of 174 outpatient children and adolescents (ages 7-17 years) with major depression ([Wagner et al. 2004b](#)). Patients were randomly assigned to receive citalopram (dosage range=20-40 mg/day; mean daily dosage=23 mg for children, 24 mg for adolescents) or placebo for an 8-week trial. Compared with the placebo group, the citalopram group showed statistically significantly greater improvement in depression (CDRS-R scores). The most frequent adverse events were headache, nausea, rhinitis, abdominal pain, and influenza-like symptoms. A European double-blind, placebo-controlled multicenter study ([von Knorring et al. 2006](#)) of citalopram in 224 adolescents with major depression failed to show

superiority of citalopram to placebo on the primary efficacy measures, the Schedule for Affective Disorders and Schizophrenia for School-Aged Children—Present Episode Version (Kiddie-SADS-P) and the Montgomery-Åsberg Depression Rating Scale (MADRS). The most commonly reported adverse events were headache, nausea, and vomiting.

## Sertraline

The efficacy of sertraline was assessed in two identical double-blind, placebo-controlled multicenter studies of 376 outpatient children and adolescents with major depression ([Wagner et al. 2003a](#)). Patients were randomly assigned to sertraline (dosage range=50–200 mg/day; mean daily dosage=131 mg) or placebo for a 10-week trial. Compared with the placebo group, the group receiving sertraline showed a statistically significantly greater improvement in depression (CDRS-R scores). Response rates (decrease  $\geq 40\%$  in baseline CDRS-R scores) were 69% in the group treated with sertraline and 59% in the group treated with placebo. The most common side effects in the group treated with sertraline were headache, nausea, insomnia, upper respiratory tract infection, abdominal pain, and diarrhea.

Sertraline, CBT, and combined CBT plus sertraline were compared in the treatment of 73 adolescents with depressive disorders ([Melvin et al. 2006](#)). All treatments resulted in statistically significant improvement on all outcome measures; there were no significant advantages of combined treatment.

In the Adolescent Depression and Psychotherapy Trial (ADAPT; [Goodyer et al. 2008](#)), 208 adolescents with major depression were randomly assigned to receive an SSRI alone or an SSRI plus CBT for 12 weeks. No significant

differences were found between the groups; 44% of the SSRI-alone group and 42% of the SSRI-plus-CBT group were much or very much improved on the CGI Improvement subscale (CGI-I).

## Paroxetine

There have been three double-blind, placebo-controlled trials of paroxetine for treatment of depression in children and adolescents, all of which had negative findings on the primary outcome measure. In a study of 275 adolescent outpatients (ages 12-18 years) with major depression, patients were randomly assigned to paroxetine (dosage range=20-40 mg/day; mean daily dosage=28 mg), imipramine (dosage range=200-300 mg/day; mean daily dosage=205 mg), or placebo for an 8-week trial ([Keller et al. 2001](#)). There was no statistically significant difference among the treatment groups on the primary efficacy measure of reduction in total score on the Hamilton Rating Scale for Depression (Ham-D). The most common side effects reported for paroxetine were headache, nausea, dizziness, dry mouth, and somnolence.

Two hundred six children and adolescents (ages 7-17 years) with major depression were included in an 8-week double-blind, placebo-controlled, randomized multicenter study of paroxetine treatment ([Emslie et al. 2006](#)). There was no statistically significant difference between patients treated with paroxetine and patients given placebo on change from baseline in CDRS-R total score at endpoint. Adverse events reported for paroxetine with an incidence of >5% and at least twice that of placebo were dizziness, cough, dyspepsia, and vomiting.

A 12-week international placebo-controlled multicenter trial of paroxetine in 286 adolescents with major depression

failed to show superiority for paroxetine compared with placebo on change from baseline in MADRS or Schedule for Affective Disorders and Schizophrenia for School-Aged Children—Lifetime Version (Kiddie-SADS-L) total score ([Berard et al. 2006](#)).

## Other Antidepressants

### Venlafaxine

Two double-blind, placebo-controlled multicenter studies have evaluated the efficacy of venlafaxine extended release (XR) in the treatment of major depression in 165 and 169 child and adolescent outpatients, respectively ([Emslie et al. 2007](#)). Patients were randomly assigned to venlafaxine XR (37.5–225 mg/day; flexible dosage based on body weight) for 8-week trials. Both studies were negative on the primary outcome measure of change from baseline to endpoint in the CDRS-R scores. The most common adverse events were anorexia and abdominal pain ([Emslie et al. 2007](#)).

### Nefazodone

There have been two double-blind, placebo-controlled multicenter trials of nefazodone in the treatment of major depression in youth ([Rynn et al. 2002](#); [U.S. Food and Drug Administration 2004b](#)). These studies failed to find statistically significant improvement in baseline-to-endpoint CDRS-R scores between the nefazodone-treated group and the placebo-treated group. The most common adverse events with nefazodone were headache, abdominal pain, nausea, vomiting, somnolence, and dizziness.

## Bupropion

There are no controlled trials of bupropion for the treatment of pediatric depression.

In an 8-week study of bupropion sustained release (dosage range=100-400 mg/day; mean daily dosage=362 mg) for treating 11 adolescents with major depression, 8 adolescents (79%) showed a 50% reduction in depression scores from baseline ([Glod et al. 2000](#)). Bupropion sustained release was assessed in an 8-week open study for the treatment of comorbid depression and ADHD in 24 adolescents ([Daviss et al. 2001](#)). Global improvement was reported in 14 subjects (58%) for both depression and ADHD and in 7 subjects (29%) for depression only. Common side effects were headache, nausea, rash, and irritability.

## Mirtazapine

There have been two double-blind, placebo-controlled multicenter trials of mirtazapine in the treatment of child and adolescent outpatients with major depression. In these studies, mirtazapine was not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores ([U.S. Food and Drug Administration 2004b](#)).

## Duloxetine

There have been two failed 10-week trials of duloxetine in the treatment of children and adolescents with major depression ([Atkinson et al. 2014](#); [Emslie et al. 2014](#)). Duloxetine and fluoxetine were not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores. The most common adverse

events were nausea, vomiting, nasopharyngitis, upper abdominal pain, headache, and somnolence.

### **Desvenlafaxine Succinate Sustained Release**

The efficacy of desvenlafaxine sustained release (SR) for the treatment of major depression in 340 children and adolescents (ages 7–17 years) was assessed in a double-blind, placebo-controlled trial ([Pfizer 2015](#)). The study had three treatment arms: desvenlafaxine SR, fluoxetine, and placebo. This was a failed study; neither desvenlafaxine SR nor fluoxetine was significantly superior to placebo.

### **Selegiline Transdermal System**

In a placebo-controlled trial of 308 adolescents with major depression, selegiline transdermal system was not superior to placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores ([DelBello et al. 2014](#)). The most common adverse events for selegiline were application site reactions, headaches, and nausea.

## **Suicidality and Black Box Warning**

In a combined analysis of 24 short-term placebo-controlled trials of antidepressant medications in child and adolescent major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders, the rates of suicidality (suicidal thinking and behavior) were 4% in patients given medication and 2% in patients given placebo. There were no suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and

behavior in children and adolescents being treated with antidepressant medications and to emphasize the need for close monitoring of patients taking the medications ([U.S. Food and Drug Administration 2004a](#)). Parents and patients should be advised of the black box warning for antidepressant medication.

In a subsequent meta-analysis of 27 trials of antidepressants in pediatric major depression, the rates of suicidal ideation and attempts were 3% in the youth treated with antidepressants and 2% in the youth who received placebo ([Bridge et al. 2007](#)). The investigators reported that the number needed to treat was 10, whereas the number needed to harm was 112, and therefore the benefits of antidepressants outweigh the potential risk from suicidal ideation or attempt.

A number of studies, in both the United States and Europe, have failed to demonstrate an association between antidepressant use and youth suicide ([Gibbons et al. 2006](#); [Markowitz and Cuellar 2007](#); [Simon et al. 2006](#); [Søndergård et al. 2006](#)). It is noteworthy that the suicide rate in youth increased following the addition of the black box warning on antidepressants ([Hamilton et al. 2007](#)). The FDA advisory has been associated with significant decreases in the rates of diagnosis and treatment of pediatric depression ([Libby et al. 2007](#)). The risk of deliberate self-harm was found to be higher in youth whose treatment was initiated with high-dosage SSRIs than in those whose treatment began with modal-dosage SSRIs ([Miller et al. 2014](#)).

## Treatment-Resistant Depression

In the National Institute of Mental Health (NIMH)-funded multisite Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) trial ([Brent et al. 2008](#)), 334 adolescents with SSRI-resistant depression were randomly assigned to one of four treatments for 12 weeks: 1) switch to an alternate SSRI (paroxetine, citalopram, or fluoxetine), 2) switch to an alternate SSRI plus CBT, 3) switch to venlafaxine, or 4) switch to venlafaxine plus CBT. CBT plus a medication switch (to venlafaxine or to an alternate SSRI) produced the highest rate of response (54.8%). Response rates (CGI-I score  $\leq 2$  and CDRS-R  $\geq 50\%$  reduction) were similar for switching to an alternate SSRI and switching to venlafaxine (47% and 48.2%, respectively). Skin problems and increases in diastolic blood pressure and pulse were more frequently experienced during venlafaxine treatment than during SSRI treatment.

## Clinical Recommendations for Major Depressive Disorder

An evidence-based consensus medication algorithm for the treatment of childhood major depression is available (Texas Children's Medication Algorithm Project [TMAP]; [Hughes et al. 2007](#)). Based on research evidence and panel discussion, four stages of medication treatment are identified:

- Stage 1: SSRI
- Stage 2: Alternate SSRI
- Stage 2A (if partial response to SSRI): SSRI+lithium, bupropion, or mirtazapine
- Stage 3: Different class of antidepressant medication (venlafaxine, bupropion, mirtazapine, duloxetine)

- Stage 4: Reassessment, treatment guidance

An additional recommendation is that antidepressants should be continued for 6–12 months after symptom remission. At the time of discontinuation of an antidepressant, the dosage should be tapered slowly (i.e., no more than 25% per week). The typical tapering and discontinuation period is 2–3 months.

---

## Bipolar Disorder

---

The prevalence of bipolar disorder in a community sample of adolescents was found to be 1% ([Merikangas et al. 2010](#)). Although DSM-5 criteria are used to diagnose bipolar disorder in youth, the clinical features in children may differ from those in adolescents and adults. Children with bipolar disorder frequently exhibit mixed mania and rapid cycling ([B. Geller et al. 2000](#)). One-year recovery rates of 87% and relapse rates of 64% have been reported in children with bipolar disorder ([B. Geller et al. 2004](#)).

Six medications have FDA approval for the acute treatment of bipolar I disorder, mixed or manic episode, in youth: lithium ( $\geq 12$  years old), aripiprazole ( $\geq 10$  years old), asenapine ( $\geq 10$  years old), olanzapine ( $\geq 13$  years old), risperidone ( $\geq 10$  years old), and quetiapine ( $\geq 10$  years old). Ziprasidone has been studied for the treatment of bipolar disorder in youth, but it does not have FDA approval for that indication.

## Lithium

The efficacy of lithium for the treatment of bipolar I disorder, manic or mixed episode, was assessed in an 8-week double-blind, placebo-controlled trial involving 81 youths (ages 7–17 years) ([Findling et al. 2015b](#)). The mean lithium serum level at endpoint was 0.98 mEq/L. Lithium was superior to placebo on the primary outcome measure of change in Young Mania Rating Scale (YMRS) score from baseline to endpoint. On CGI-I scores, 47% of lithium-treated and 21% of placebo-treated patients were much or very much improved. The most common adverse events with lithium were vomiting, nausea, and headache. There was a statistically significant increase in thyrotropin concentration with lithium.

In an NIMH-funded study, 153 children and adolescents with bipolar I disorder, mixed or manic episode, were randomly assigned to treatment with lithium, divalproex, or placebo in an 8-week trial ([Kowatch et al. 2007](#)). Target lithium serum levels were 0.8–1.2 mEq/L. Lithium was not significantly superior to placebo.

There is one small double-blind, placebo-controlled study of lithium treatment for adolescent bipolar disorder and DSM-III-R ([American Psychiatric Association 1984](#))-defined substance dependence ([B. Geller et al. 1998](#)). Twenty-five adolescent outpatients were randomly assigned to either lithium (mean serum level=0.97 mEq/L) or placebo for a 6-week trial. There was significantly greater improvement in global functioning with lithium than with placebo. Side effects in the group treated with lithium were polyuria, thirst, nausea, vomiting, and dizziness.

## Atypical Antipsychotics

## Aripiprazole

The efficacy of aripiprazole was assessed in a 4-week double-blind, placebo-controlled trial that included 296 youths with bipolar I disorder, mixed or manic episode ([Findling et al. 2009](#)). Both low-dosage aripiprazole (10 mg/day) and high-dosage aripiprazole (30 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate ( $\geq 50\%$  reduction in YMRS score) was 44.8% for low-dosage aripiprazole, 63.6% for high-dosage aripiprazole, and 26.1% for placebo. The most common adverse events with aripiprazole were somnolence, extrapyramidal side effects (EPS), and tremor, which were more frequent in the high-dosage aripiprazole group.

## Asenapine

The efficacy of asenapine was evaluated in a 3-week, double-blind, placebo-controlled trial of 403 youths (ages 10–17 years) with bipolar I disorder, mixed or manic episode ([Actavis 2017](#)). Dosages ranged from 2.5 to 10 mg twice daily. Asenapine was significantly superior to placebo on outcome measures of change in YMRS and CGI Bipolar (CGI-BP) Severity of Illness scores from baseline to endpoint. The most common adverse events were somnolence, dizziness, oral hypoesthesia, headache, fatigue, and increased appetite.

## Olanzapine

There is one reported double-blind, placebo-controlled multicenter study of olanzapine (2.5–20 mg/day) in the treatment of adolescent outpatients with bipolar I disorder, mixed or manic episode ([Tohen et al. 2007](#)). Adolescents

were randomly assigned to receive olanzapine ( $n=107$ ) or placebo ( $n=54$ ) for 3 weeks. Response rates (defined as  $\geq 50\%$  decrease in YMRS score) were significantly greater for the olanzapine group (44.8%) than for the placebo group (18.5%). Remission rates (defined as YMRS score  $<12$ ) were significantly greater for the olanzapine group (35.2%) than for the placebo group (11.1%). Adverse effects in the olanzapine group were hyperprolactinemia, weight gain (mean=3.7 kg), somnolence, and sedation.

## Risperidone

In a 3-week double-blind, placebo-controlled trial, the efficacy of risperidone was assessed in 169 children and adolescents with bipolar I disorder, manic or mixed episode ([Haas et al. 2009](#)). Both low-dosage risperidone (0.5–2.5 mg/day) and high-dosage risperidone (3–6 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate ( $\geq 50\%$  reduction in baseline YMRS score) was 59% for low-dosage risperidone and 63% for high-dosage risperidone, compared with a placebo response rate of 26%. The most common adverse events with risperidone were somnolence, headache, and fatigue. EPS were more frequent in the high-dosage risperidone group than in the low-dosage group.

## Quetiapine

In a 3-week double-blind, placebo-controlled trial, the efficacy of quetiapine was assessed in 277 youths with bipolar I disorder, manic or mixed episode ([DelBello et al. 2007](#)). Both low-dosage quetiapine (400 mg/day) and high-dosage quetiapine (600 mg/day) were significantly superior to placebo in reduction of YMRS scores. The response rate

( $\geq 50\%$  reduction in baseline YMRS score) was 64% for low-dosage quetiapine, 58% for high-dosage quetiapine, and 37% for placebo. The most common adverse events with quetiapine were somnolence, sedation, dizziness, and headache.

## **Ziprasidone**

The efficacy of ziprasidone was assessed in a 4-week double-blind, placebo-controlled trial that included 150 youths with bipolar I disorder, manic or mixed episode ([DelBello et al. 2008](#)). Ziprasidone dosages ranged from 80 to 160 mg/day. Ziprasidone was significantly superior to placebo in reduction of YMRS scores. The response rate ( $\geq 50\%$  reduction in YMRS score) was 62% for ziprasidone and 35% for placebo. The most common side effects with ziprasidone were sedation, somnolence, nausea, fatigue, and dizziness.

# **Anticonvulsants**

## **Divalproex**

A 4-week double-blind, placebo-controlled multicenter trial of 150 youths (ages 10–17 years) with bipolar I disorder, mixed or manic episode, did not show a significant difference in YMRS scores from baseline to endpoint for those patients given divalproex extended release (ER) and those given placebo ([Wagner et al. 2009](#)). The mean modal dose of divalproex ER was 1,286 mg. There were no statistically significant differences in adverse-event incidents between the divalproex ER and placebo groups.

Gastrointestinal symptoms were more commonly reported in divalproex ER than in placebo groups.

## **Carbamazepine**

In an open-label study of carbamazepine ER for 137 youths (ages 10–17 years) with bipolar I disorder, mixed or manic episode, there was a statistically significant reduction in scores on the YMRS from baseline to endpoint ([Findling and Ginsberg 2014](#)). At endpoint, the most prevalent dosage of carbamazepine ER was 1,200 mg/day. The most common adverse events were rash, decreased white blood cell count, nausea, and vomiting.

## **Oxcarbazepine**

The only double-blind, placebo-controlled multicenter trial of oxcarbazepine for the treatment of children and adolescents with bipolar I disorder, current episode mixed or manic, failed to show superiority of oxcarbazepine over placebo. The researchers randomly assigned 116 youths (ages 7–18 years) to receive oxcarbazepine (mean dosage=1,515 mg/day) or placebo for a 7-week trial ([Wagner et al. 2006b](#)). There was no significant difference in YMRS scores at endpoint between the oxcarbazepine and placebo groups. The most common side effects in the oxcarbazepine-treated patients were dizziness, nausea, somnolence, diplopia, fatigue, and rash.

## **Topiramate**

A double-blind, randomized, placebo-controlled multicenter study assessing the efficacy of topiramate treatment in children and adolescents with acute mania was designed as a 200-patient study but was terminated after randomization

of 56 patients (ages 6–17 years) when adult mania trials failed to show efficacy ([DelBello et al. 2005](#)). Dosages were titrated to 400 mg/day (mean dosage=278 mg/day). Over a 4-week period, no significant difference was found between the topiramate and placebo groups. The most common adverse events in the topiramate group included decreased appetite, nausea, diarrhea, paresthesias, and somnolence.

## Lamotrigine

In a 12-week open-label trial, the efficacy of lamotrigine was assessed in 30 children and adolescents with bipolar spectrum disorders ([Biederman et al. 2010](#)). The mean lamotrigine dosage at endpoint was 160.7 mg/day. Significant improvement in mean YMRS scores was reported; however, only about half the participants completed the trial, and seven participants discontinued lamotrigine because of rash.

## Comparator Studies

The Treatment of Early Age Mania (TEAM) study compared the effectiveness of risperidone, lithium, and divalproex in the treatment of 279 youths (ages 6–15 years) with bipolar I disorder, manic or mixed episode ([B. Geller et al. 2012](#)). Response was defined as a CGI-BP-Improvement Mania score of 2 or lower. The mean lithium level was 1.09 mEq/L, the mean divalproex level was 113.6 µg/mL, and the mean risperidone dosage was 2.57 mg/day. The risperidone response rate (68.5%) was significantly higher than response rates for lithium (35.6%) and divalproex (24%). There was no significant difference between lithium and divalproex response rates. Increased weight gain, body

mass index (BMI), and prolactin levels occurred significantly more frequently with risperidone than with lithium or divalproex.

Similarly, a comparator analysis of the efficacy of antipsychotics and mood stabilizers for the treatment of pediatric bipolar disorder showed significantly greater improvement in YMRS scores for patients given antipsychotics than for those given mood stabilizers ([Correll et al. 2010](#)). Effect sizes were 0.65 for antipsychotics and 0.24 for mood stabilizers.

The comparative efficacy of lithium, divalproex, and carbamazepine was assessed in a 6-week randomized open-label trial involving 42 children and adolescents with bipolar disorder ([Kowatch et al. 2000b](#)). There were no significant differences in response rates ( $\geq 50\%$  reduction in YMRS score) among the groups given lithium (38%), divalproex (53%), and carbamazepine (38%).

The comparative efficacy of risperidone and divalproex was assessed in an 8-week double-blind, randomized trial in 66 children and adolescents with bipolar disorder ([Pavuluri et al. 2010](#)). Significantly higher response rates ( $\geq 50\%$  reduction in YMRS) were found for risperidone (78.1%) than for divalproex (45.5%), and improvement was more rapid in risperidone-treated patients than in divalproex-treated patients.

The comparative efficacy of quetiapine and divalproex was assessed in a 4-week double-blind, placebo-controlled trial involving 50 adolescents with bipolar I disorder, manic or mixed episode ([DelBello et al. 2006](#)). No significant group differences were found in YMRS scores during the trial.

In an 8-week open-label trial, the efficacies of olanzapine and risperidone were compared in preschool-age children

with bipolar disorder ([Biederman et al. 2005](#)). There were no significant differences in response rates between risperidone (69%) and olanzapine (53%).

In a 6-week placebo-controlled trial of valproic acid versus risperidone for children (ages 3–7 years) with bipolar disorder, manic, mixed or hypomanic episode, risperidone was superior to placebo on reduction in YMRS scores from baseline to endpoint. There was no significant difference found between valproic acid and placebo ([Kowatch et al. 2015](#)).

## Combination Treatment

Some children with bipolar disorder may not respond to initial monotherapy treatment or may need combination treatment over the course of the illness. For example, in a study by [Kowatch et al. \(2000a\)](#), following acute 6-week treatment with one mood stabilizer, 20 of 35 youths (58%) required additional psychotropic medication over the next 16 weeks. The response rate to combination treatment with two mood stabilizers was high (80%) for those youths who did not respond to monotherapy.

The FDA has approved the use of quetiapine or aripiprazole as an adjunct to lithium or valproate treatment in children ages 10 years and older with bipolar I disorder, mixed or manic episode.

The effectiveness of combination treatment with lithium and divalproex was assessed in an open trial ([Findling et al. 2003](#)). Ninety youths (ages 5–17 years) with bipolar I or II disorder were treated for up to 20 weeks with divalproex (mean blood level=79.8 µg/mL) and lithium (mean blood level=0.9 mmol/L). The clinical remission rate (defined as

contiguous weekly ratings of YMRS scores  $\leq 12.5$ , CDRS-R scores  $\leq 40$ , Children's Global Assessment Scale [CGAS] scores  $\geq 51$ , clinical stability, and no mood cycling) was 42%.

The efficacy of risperidone in combination with lithium or divalproex was assessed in a 6-month open-label trial ([Pavuluri et al. 2004](#)). Thirty-seven youths (ages 5–18 years) with bipolar I disorder, manic or mixed episode, received either risperidone (mean dosage=0.75 mg/day) plus divalproex (mean serum level=106  $\mu\text{g/mL}$ ) or risperidone (mean dosage=0.70 mg/day) plus lithium (mean serum level=0.9 mEq/L). Response rates ( $\geq 50\%$  reduction in baseline YMRS scores) were similar for both combinations: 80% for divalproex plus risperidone, and 82.4% for lithium plus risperidone. There were no significant differences between the groups in safety and tolerability.

Risperidone augmentation for lithium nonresponders was assessed in a 1-year open-label study ([Pavuluri et al. 2006](#)). Twenty-one of 38 youths (ages 4–17 years) who failed to respond to lithium monotherapy or relapsed after initial response were given risperidone (mean dosage=0.99 mg/day) for 11 months. Response rates in the lithium plus risperidone group were 85.7%.

In a double-blind, placebo-controlled study of quetiapine, 30 adolescents with bipolar disorder received divalproex (20 mg/kg) and were randomly assigned to adjunctive quetiapine (mean daily dosage=432 mg) or placebo for 6 weeks ([DelBello et al. 2002](#)). Response rates ( $\geq 50\%$  reduction in baseline YMRS score) were significantly higher in the group receiving divalproex and quetiapine (87%) than in the group receiving divalproex and placebo (53%).

## Maintenance Treatment

Sixty youths who had responded to a combination of lithium and divalproex in a 20-week trial were randomly assigned in a double-blind trial to either lithium or divalproex for 18 months ([Findling et al. 2005](#)). There was no significant difference in the time to relapse between the groups (median days: divalproex 112, lithium 114).

## Clinical Recommendations for Bipolar Disorder

Treatment guidelines were developed by expert consensus and review of the available treatment literature for children and adolescents (ages 6–17 years) with bipolar I disorder, manic or mixed episode ([Kowatch et al. 2005](#)). Six stages were identified:

- Stage 1: Monotherapy with mood stabilizer or atypical antipsychotic
- Stage 2: Switch monotherapy agent (drug class not tried in stage 1)
- Stage 3: Switch monotherapy agent (drug class not tried in stage 1 or 2) OR combination treatment (2 agents)
- Stage 4: Combination treatment (2 agents) OR combination treatment (3 agents)
- Stage 5: Alternative monotherapy (drugs not tried in stages 1, 2, 3)
- Stage 6: Electroconvulsive therapy (adolescents) or clozapine

If a child fails to respond to treatment in one stage, the clinician should move to the next stage of treatment. For treatment of bipolar I disorder, manic or mixed episode

with psychosis, the recommendation for initial treatment is a mood stabilizer plus an atypical antipsychotic. A minimum of 4–6 weeks at therapeutic blood levels and/or adequate dosages for each medication is recommended. Following sustained remission of at least 12–24 months, medication taper should be considered.

---

## Anxiety Disorders

---

DSM-5 anxiety disorders include generalized anxiety disorder, social anxiety disorder, panic disorder, selective mutism, agoraphobia, specific phobia, and separation anxiety disorder. Obsessive-compulsive disorder and posttraumatic stress disorder are now in separate DSM-5 categories (Obsessive-Compulsive and Related Disorders and Trauma- and Stressor-Related Disorders, respectively).

### Generalized Anxiety Disorder

The prevalence of generalized anxiety disorder (GAD) in children and adolescents is estimated to range from 2.9% to 7.3% ([Anderson et al. 1987](#); [Kashani and Orvaschel 1988](#); [Merikangas et al. 2010](#)). Children with GAD have excessive anxiety and worry about several events or activities (e.g., school performance), have difficulty controlling the worry, and have at least one associated symptom, such as restlessness, fatigue, concentration difficulties, irritability, muscle tension, and sleep disturbance ([American Psychiatric Association 2013](#)). The course of GAD in youth tends to be chronic ([Keller et al. 1992](#)).

## Duloxetine

Duloxetine has been approved by the FDA for the treatment of GAD in youths ages 7–17 years.

The efficacy of duloxetine was assessed in a 10-week double-blind, placebo-controlled trial for 272 youths (ages 7–17 years) with GAD ([Strawn et al. 2015](#)). Duloxetine was flexibly dosed from 30 to 120 mg/day. The primary efficacy measure was the Pediatric Anxiety Rating Scale (PARS). Duloxetine was significantly superior to placebo on improvement in PARS scores from baseline to endpoint. Response (defined as 50% improvement on PARS severity for GAD) and remission (defined as a PARS severity for GAD  $\leq 8$ ) were significantly greater for the duloxetine group (59% and 50%, respectively) than the placebo group (42% and 34%, respectively). Adverse events reported with significantly greater frequency for the duloxetine group than for the placebo group were nausea, vomiting, decreased appetite, oropharyngeal pain, dizziness, cough, and palpitations.

## Venlafaxine

The efficacy of venlafaxine XR in children and adolescents with GAD ( $N=320$ ) was evaluated in two double-blind, placebo-controlled trials ([Rynn et al. 2007](#)). Venlafaxine was given at dosages up to 225 mg/day. In one study, venlafaxine XR was superior to placebo on primary and secondary measures; however, in the other study, the results were negative.

## Sertraline

Twenty-two children and adolescents (ages 5–17 years) with GAD were randomly assigned to sertraline or placebo

in a 9-week double-blind trial ([Rynn et al. 2001](#)). The maximum dosage of sertraline was 50 mg/day. Significant differences in favor of sertraline over placebo were observed on the Hamilton Anxiety Scale (Ham-A) scores and on CGI Severity of Illness (CGI-S) and CGI-I ratings. Side effects found to be more common (but not statistically significantly so) with sertraline than with placebo were dry mouth, drowsiness, leg spasm, and restlessness.

## **Buspirone**

The efficacy of buspirone was evaluated for 559 youths (ages 6–17 years) with GAD who participated in a 6-week randomized placebo-controlled trial ([Bristol-Myers Squibb 2010](#)). Buspirone dosages ranged from 15 to 60 mg/day. There was no statistically significant difference in outcome between buspirone and placebo.

# **Social Anxiety Disorder (Social Phobia)**

The prevalence of social anxiety disorder (social phobia) in adolescents is reported to be 9.1% ([Merikangas et al. 2010](#)). The DSM-5 diagnostic criteria for social anxiety disorder are the same for children and adolescents as for adults. Social anxiety disorder in youth is a chronic condition, and it increases the risk of depression ([Stein et al. 2001](#)).

## **Selective Serotonin Reuptake Inhibitors**

**Paroxetine.** The efficacy and safety of paroxetine were evaluated in a 16-week double-blind, placebo-controlled

multicenter trial in 322 outpatient children and adolescents (ages 8–17 years) with social anxiety disorder ([Wagner et al. 2004a](#)). Paroxetine was significantly superior to placebo, with rates of response (defined as CGI-I score=1 or 2) of 77.6% and 38.3%, respectively. Side effects more common with paroxetine than with placebo were insomnia, decreased appetite, and vomiting.

**Fluoxetine.** The efficacy of fluoxetine was evaluated in a 12-week randomized trial of fluoxetine (up to 40 mg/day), Social Effectiveness Therapy for Children (SET-C), and placebo for 80 youths (ages 7–17 years) with social anxiety disorder ([Beidel et al. 2007](#)). Both fluoxetine and SET-C were superior to placebo in reducing social stress and behavioral avoidance and increasing general functioning.

**Sertraline.** Fourteen outpatient children and adolescents (ages 10–17 years) with a diagnosis of social anxiety disorder received sertraline (dosage range=100–200 mg/day; mean daily dosage=123 mg) in an 8-week open trial ([Compton et al. 2001](#)). Five of the patients (36%) were much or very much improved, and four of the patients (29%) had a partial response by the end of the 8-week trial. Sertraline was well tolerated, and no patient developed significant behavioral disinhibition or mania ([Compton et al. 2001](#)).

**Escitalopram.** Twenty children with social anxiety disorder participated in a 12-week open-label study of escitalopram ([Isolan et al. 2007](#)). Sixty-five percent of participants were much or very much improved.

**Citalopram.** [Chavira and Stein \(2002\)](#) investigated the effectiveness of a combined psychoeducational and

pharmacological treatment program for youth with social anxiety disorder. Twelve children and adolescents (ages 8–17 years) with social anxiety disorder received citalopram (mean daily dosage=35 mg) and eight 15-minute counseling sessions over a 12-week period. On the basis of clinical global ratings of change, five of the patients (41.7%) were very much improved, and five of the patients (41.7%) were much improved.

## **Venlafaxine**

In a 16-week double-blind, placebo-controlled trial, 293 children and adolescents with social anxiety disorder were randomly assigned to venlafaxine XR (dosage range=37.5–225 mg) or placebo ([March et al. 2007](#)). Venlafaxine XR was significantly superior to placebo in reducing ratings of social anxiety. Response rates (CGI-I score  $\leq 2$ ) were 56% for the venlafaxine XR group and 37% for the placebo group.

## **Panic Disorder**

The prevalence of panic disorder in children and adolescents ranges from 0.6% to 5.0% in the community and from 0.2% to 9.6% in clinical settings ([Masi et al. 2001](#)). The DSM-5 diagnostic criteria for panic disorder in children and adolescents are the same as those for adults. Panic disorder in youth is a chronic condition, and there is continuity between pediatric and adult panic disorder ([Biederman et al. 1997](#)).

## **Selective Serotonin Reuptake Inhibitors**

In an open-label trial, 12 children and adolescents (ages 7–17 years) with panic disorder were treated with an SSRI for 6–8 weeks ([Renaud et al. 1999](#)). Mean daily dosages of SSRIs were fluoxetine 34 mg, paroxetine 20 mg, and sertraline 125 mg. Adjunctive benzodiazepines were used for 8 patients. Seventy-five percent of patients showed much to very much clinical improvement while receiving treatment with SSRIs. At the end of the trial, 8 patients (67%) no longer fulfilled panic disorder criteria.

**Paroxetine.** A chart review was conducted of 18 child and adolescent outpatients (ages 7–16 years) with a diagnosis of panic disorder who received monotherapy with paroxetine (dosage range=10–40 mg/day; mean daily dosage=23 mg) ([Masi et al. 2001](#)). The mean paroxetine treatment duration was 11.7 months. Fifteen patients (83%) had a CGI score of much or very much improved. The most common side effects were nausea, tension-agitation, sedation, insomnia, palpitations, and headache.

**Citalopram.** Three youths (ages 9, 13, and 16 years) with panic disorder and school phobia were treated with citalopram (up to 20 mg/day) over an 8- to 15-month period. All patients experienced resolution of panic attacks during the course of citalopram treatment ([Lepola et al. 1996](#)).

## **Benzodiazepines**

In a 2-week open trial, four adolescents with panic disorder were treated with clonazepam (0.5 mg twice daily). A significant reduction in panic attacks (from 3 attacks per week to 0.25 per week) was reported ([Kutcher and MacKenzie 1988](#)).

# Mixed Anxiety Disorders

## Selective Serotonin Reuptake Inhibitors

**Fluvoxamine.** One hundred twenty-eight outpatient children and adolescents (ages 6–17 years) with GAD, social anxiety disorder, or separation anxiety disorder (who had received 3 weeks of open treatment with supportive psychoeducational therapy without improvement) were randomly assigned to fluvoxamine (up to 300 mg) or placebo for an 8-week trial ([Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001](#)). The group treated with fluvoxamine had a significantly greater reduction in scores on the PARS than did the group treated with placebo. The response rate (CGI-I score  $\leq 3$ ) was 76% in the group being treated with fluvoxamine and 29% in the group receiving placebo. After completion of the 8-week placebo-controlled study, the 128 patients entered a 6-month open-label treatment phase ([Walkup et al. 2002](#)). Anxiety symptoms remained low in 33 of 35 of the subjects (94%) who initially responded to fluvoxamine. Of 14 fluvoxamine nonresponders switched to fluoxetine, anxiety symptoms significantly improved in 10 patients (71%). Among 48 placebo nonresponders, 27 (56%) showed significant improvement in anxiety on fluvoxamine.

**Fluoxetine.** Seventy-four youths (ages 7–17 years) with GAD, separation anxiety disorder, and/or social phobia were randomly assigned to fluoxetine (20 mg/day) or to placebo for 12 weeks ([Birmaher et al. 2003](#)). Sixty-one percent of fluoxetine-treated patients and 35% of placebo-treated patients were much or very much improved.

Fluoxetine's efficacy in long-term treatment of children with GAD, separation anxiety disorder, and/or social phobia was assessed in a 1-year open treatment ([Clark et al. 2005](#)) following the acute-phase study ([Birmaher et al. 2003](#)). Compared with youth taking no medication, those taking fluoxetine ( $n=42$ ) showed significantly superior outcome in anxiety measures.

The comparative efficacy of fluoxetine and clomipramine was evaluated in a 12-week double-blind, randomized, placebo-controlled trial for 36 youths (ages 7-17 years) with GAD, separation anxiety, and/or social anxiety disorder ([da Costa et al. 2013](#)). Although all groups showed significant improvement, no significant difference was found between fluoxetine and placebo or between clomipramine and placebo.

**Sertraline.** The comparative efficacy of sertraline, CBT, sertraline plus CBT, and placebo was evaluated in a 12-week randomized controlled trial (the Child Anxiety Multimodal Study [CAMS]) involving 488 children and adolescents with a diagnosis of GAD, separation anxiety disorder, or social phobia ([Walkup et al. 2008](#)). Combination treatment was significantly superior to sertraline alone or CBT alone. Rates of response (CGI-I score  $\leq 2$ ) were 80.7% for combined treatment, 59.7% for CBT, and 54.9% for sertraline. All treatments were significantly superior to placebo (23.7%).

Long-term outcomes from the CAMS study have been reported ([Piacentini et al. 2014](#)). At 24 and 36 weeks, most ( $\geq 80\%$ ) of the acute responders maintained a positive response. Combination treatment maintained an advantage over CBT and sertraline alone.

# Clinical Recommendations for Anxiety Disorders

In regard to childhood anxiety disorders, SSRIs are the first-line treatment ([Reinblatt and Walkup 2005](#)). Duloxetine and venlafaxine also have demonstrated efficacy for the treatment of childhood GAD. Other treatment options include buspirone, tricyclic antidepressants, and benzodiazepines ([Bernstein et al. 1996](#)). However, benzodiazepines should be used only on a short-term basis (i.e., weeks) because of the potential for abuse and dependence in youth ([Riddle et al. 1999](#)).

---

## Obsessive-Compulsive Disorder

---

OCD has a prevalence rate of 2%–4% in youth ([Douglass et al. 1995](#); [Zohar 1999](#)). The DSM-5 criteria for OCD are the same in children and adults. The course of OCD in youth is chronic.

## Serotonin Reuptake Inhibitors

Four medications have received FDA approval for the treatment of OCD in children and adolescents: sertraline ( $\geq 6$  years old), fluoxetine ( $\geq 7$  years old), fluvoxamine ( $\geq 7$  years old), and clomipramine ( $\geq 10$  years old). Citalopram and paroxetine have been studied for treatment of OCD in youth but do not have FDA approval.

### Sertraline

In a double-blind, placebo-controlled multicenter study, 187 children and adolescents (ages 6–17 years) with OCD were randomly assigned to sertraline or placebo ([March et al. 1998](#)). Sertraline dosages were titrated to a maximum of 200 mg/day during the first 4 weeks of the trial, and these dosages were maintained for an additional 8 weeks. The mean dosage of sertraline was 167 mg/day at endpoint. Compared with patients receiving placebo, patients receiving sertraline showed significantly greater improvement on the CY-BOCS, the NIMH Global Obsessive Compulsive Rating Scale (NIMH GOCS), and the CGI-S and CGI-I subscales. Forty-two percent of patients in the sertraline group and 26% of patients in the placebo group were rated as very much or much improved. Side effects of insomnia, nausea, agitation, and tremor occurred significantly more often in the group receiving sertraline than in the group receiving placebo.

In an assessment of the long-term safety and effectiveness of sertraline for pediatric OCD, 137 patients who completed the 12-week double-blind, placebo-controlled sertraline study ([March et al. 1998](#)) were given open-label sertraline (mean dosage=120 mg/day) in a 52-week extension study. Significant improvement was found on CY-BOCS, NIMH GOCS, and CGI scores. Rates of response (defined as >25% decrease in CY-BOCS and a CGI-I score of 1 or 2) were 72% for children and 61% for adolescents ([Cook et al. 2001](#)). Full remission (defined as a CY-BOCS score <8) was achieved in 47% of patients, and an additional 25% achieved partial remission (CY-BOCS score >8 but <15) ([Wagner et al. 2003b](#)). The most common side effects were headache, nausea, diarrhea, somnolence, abdominal pain, hyperkinesias, nervousness, dyspepsia, and vomiting.

The relative and combined efficacy of sertraline and CBT was assessed in a 12-week trial for 112 children and adolescents (ages 7–17 years) with OCD ([Pediatric OCD Treatment Study \[POTS\] Team 2004](#)). Patients were randomly assigned to sertraline, CBT, combined sertraline and CBT, or placebo. Combined treatment was significantly superior to CBT alone and sertraline alone, which did not differ from each other.

The efficacy of sequential sertraline and CBT compared with CBT and placebo was assessed in an 18-week trial for 47 youths (ages 7–17 years) with OCD ([Storch et al. 2013](#)). No significant difference was found between the groups on improvement in OCD symptoms.

## **Fluoxetine**

The safety and efficacy of fluoxetine were assessed in a 13-week double-blind, placebo-controlled multicenter trial ([D.A. Geller et al. 2001](#)). One hundred three children and adolescents (ages 7–17 years) with OCD were randomly assigned in a 2:1 ratio to either fluoxetine (dosage range=10–60 mg/day; mean daily dosage=24.6 mg) or placebo. The group treated with fluoxetine showed a statistically significant reduction in OCD severity compared with the group treated with placebo, as determined by changes in CY-BOCS scores. Rates of response (defined as >40% reduction in CY-BOCS score) were 49% in the fluoxetine group and 25% in the placebo group. There were no significant differences in treatment-emergent adverse events between the fluoxetine and placebo groups.

Fluoxetine was compared with placebo in a controlled trial in 43 children and adolescents with OCD ([Liebowitz et al. 2002](#)). After 16 (but not 8) weeks of treatment, the

fluoxetine group had significantly lower CY-BOCS scores than the placebo group.

## **Fluvoxamine**

The safety and efficacy of fluvoxamine were evaluated in a double-blind, placebo-controlled multicenter study ([Riddle et al. 2001](#)). One hundred twenty outpatient children and adolescents (ages 8-17 years) with OCD were randomly assigned to receive fluvoxamine (dosage range=50-200 mg/day; mean daily dosage=165 mg) or placebo for a 10-week trial. Patients who did not respond after 6 weeks could discontinue the double-blind phase and enter an open-label trial of fluvoxamine. Mean scores on the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) were significantly different for the fluvoxamine and the placebo groups at weeks 1, 2, 3, 4, 6, and 10. Response rates (>25% reduction in CY-BOCS scores) were 42% in the group being treated with placebo. Adverse events occurring at a placebo-adjusted frequency of greater than 10% were insomnia and asthenia.

In an assessment of the safety and effectiveness of fluvoxamine in the long-term treatment of pediatric OCD, 99 patients who completed the acute double-blind, placebo-controlled fluvoxamine study by [Riddle et al. \(2001\)](#) participated in a 1-year open-label extension study ([Walkup et al. 1998](#)). Fluvoxamine dosages were titrated to 200 mg/day over the first 4 weeks. Patients experienced a 42% reduction in CY-BOCS scores by the end of long-term treatment. Clinical improvement plateaued at about 6 months of treatment. The most common side effects of fluvoxamine were insomnia, asthenia, nausea, hyperkinesias, and nervousness.

## Clomipramine

Clomipramine has been shown to be efficacious in the treatment of pediatric OCD in two double-blind, placebo-controlled trials. In the first study ([Flament et al. 1985](#)), 19 children (ages 10–18 years) with OCD were randomly assigned to clomipramine (dosage range=100–200 mg/day; mean daily dosage=141 mg) or placebo for 5 weeks. Significant improvement in observed and self-reported obsessions and compulsions was found for patients who received clomipramine. The most common side effects with clomipramine were tremor, dry mouth, dizziness, and constipation. One patient had a grand mal seizure.

In an 8-week double-blind, placebo-controlled multicenter study of 60 children and adolescents (ages 10–17 years) with OCD, it was found that patients who received clomipramine (up to 200 mg/day) had significantly greater reductions in scores on the CY-BOCS than the placebo group (37% and 8%, respectively). Forty-seven patients continued in a 1-year open-label extension trial, and effectiveness was maintained with long-term treatment. The most frequent side effects with clomipramine were dry mouth, somnolence, dizziness, fatigue, tremor, headache, constipation, and anorexia ([DeVeugh-Geiss et al. 1992](#)).

## Citalopram

Twenty-three child and adolescent outpatients (ages 9–18 years) with OCD were administered open-label citalopram (dosage range=10–40 mg/day; mean daily dosage=37 mg) in a 10-week trial ([Thomsen 1997](#)). There was a statistically significant improvement in CY-BOCS scores from baseline to endpoint. Adverse effects were minimal and transient.

In an 8-week open-label citalopram study of 15 youths (ages 6–17 years) with OCD, 14 patients showed significant improvement in CY-BOCS scores from baseline to endpoint ([Mukaddes and Abali 2003](#)).

In a long-term open study of 30 adolescents with OCD, citalopram (dosage range=20–70 mg/day; mean daily dosage=46.5 mg) was administered for 1–2 years ([Thomsen et al. 2001](#)). There was a significant reduction in CY-BOCS scores from baseline to assessment at 2 years. No serious adverse events were reported, and the most common side effects were sedation, sexual dysfunction, and weight gain.

## **Paroxetine**

The efficacy and safety of paroxetine were assessed in a double-blind, placebo-controlled multicenter study of 203 outpatient children and adolescents (ages 7–17 years) with OCD ([D.A. Geller et al. 2004](#)). Patients were randomly assigned to paroxetine (dosage range=10–50 mg/day; mean daily dosage=23 mg) or placebo for a 10-week trial. There was a statistically significant greater reduction in CY-BOCS scores from baseline to endpoint in patients treated with paroxetine than in patients treated with placebo. Response rates (>25% reduction in CY-BOCS scores) were 64.9% in the paroxetine-treated patients and 41.2% in the placebo-treated patients. The most common adverse effects in the paroxetine group were headache, abdominal pain, nausea, respiratory disorder, somnolence, hyperkinesias, and trauma.

The efficacy of paroxetine in 335 outpatients (ages 7–17 years) with OCD was assessed in a 16-week open-label multicenter study of paroxetine (10–60 mg/day), followed by double-blind randomization of responders to paroxetine or placebo for an additional 16 weeks ([Emslie et al. 2000](#)).

No significant differences in response rates were found between the group receiving paroxetine and the group receiving placebo in the randomization phase.

## Atypical Antipsychotic Augmentation

Adjunctive risperidone ( $\leq 2$  mg daily) was investigated in an open trial for 17 adolescents with OCD who failed to respond to two serotonin reuptake inhibitor monotherapy trials. A significant reduction in CY-BOCS scores was reported ([Thomsen 2004](#)).

Aripiprazole augmentation of CBT was found to be effective in the case of an adolescent who had a partial response to combined CBT and sertraline ([Storch et al. 2008](#)).

In a naturalistic sample of 220 children and adolescents with OCD, 43 children were treated with an atypical antipsychotic as an augmenting agent ([Masi et al. 2009](#)). Twenty-five of these youths (58.1%) responded to treatment.

The efficacy of aripiprazole augmentation of an SSRI was assessed in 39 youths with OCD who had not responded to two trials with SSRI monotherapy ([Masi et al. 2010](#)). Fifty-nine percent of the youths responded to treatment.

## Other Agents

### D-Cycloserine

Augmentation of CBT with D-cycloserine was evaluated in a double-blind, placebo-controlled trial for 30 youths (ages 8–

17 years) with OCD. No significant differences were found between treatment groups ([Storch et al. 2010](#)).

D-Cycloserine-augmented CBT was assessed in a double-blind, placebo-controlled pilot trial for 17 youths with difficult-to-treat OCD ([Farrell et al. 2013](#)). The augmented CBT resulted in greater improvement in OCD symptoms than CBT plus placebo.

## **Riluzole**

Sixty children and adolescents with treatment-resistant OCD participated in a 12-week double-blind, placebo-controlled trial of add-on riluzole or placebo with current treatment ([Grant et al. 2014](#)). The riluzole final dosage was 100 mg/day. All participants significantly improved on CY-BOCS ratings, and there was no significant difference between riluzole and placebo on any outcome measures. Adverse events reported for patients given riluzole included one case of pancreatitis and five instances of slight increase with transaminases.

## **N-Acetylcysteine**

The authors of a case report ([Yazici and Percinel 2014](#)) and a case series ([Yazici and Percinel 2015](#)) describe the use of N-acetylcysteine (NAC) augmentation for treatment-resistant OCD in children and adolescents. NAC dosages were initiated at 600 mg/day and increased up to 2,400–3,000 mg/day. Improvement in OCD symptoms was found in some cases.

# **Clinical Recommendations for Obsessive-Compulsive Disorder**

SSRIs are the medication treatment of choice for OCD in children and adolescents ([American Academy of Child and Adolescent Psychiatry 2012](#)). Clomipramine is also effective in the treatment of this disorder; however, it is not a first-line treatment because of its adverse-event profile. A 12-week trial at an adequate dosage is indicated to determine whether a child with OCD will respond to an SSRI. If a child fails to respond to one SSRI, switching to another SSRI is a reasonable strategy. Clomipramine, either as monotherapy or as augmentation of an SSRI, may be a third treatment option. Other possible SSRI augmentation strategies are clonazepam and atypical antipsychotics; however, these agents have not received systematic study. Some children may require long-term medication maintenance; however, it is reasonable to attempt medication discontinuation 1 year after symptom stabilization. Medication should be tapered gradually to assess for relapse. Two or three relapses should lead to long-term treatment.

---

## Posttraumatic Stress Disorder

---

The prevalence of posttraumatic stress disorder (PTSD) in adolescents is reported to be 5% ([Merikangas et al. 2010](#)). The criteria for diagnosing PTSD in children older than age 6 years are the same as those used for adults ([American Psychiatric Association 2013](#)). PTSD symptoms in children tend to vary over time, and although the disorder is chronic, the course is prolonged with greater severity of the stressor ([Clarke et al. 1993](#)).

# Sertraline

The efficacy of sertraline was evaluated in a 10-week double-blind, placebo-controlled trial in 131 children and adolescents with PTSD ([Robb et al. 2010](#)). Sertraline dosages ranged from 50 to 200 mg/day. There was no difference between sertraline-treated patients and placebo-treated patients in scores on the primary outcome measure, the University of California, Los Angeles Post-Traumatic Stress Disorder Index for DSM-IV (UCLA PTSD-I).

The benefit of adding sertraline versus placebo to trauma-focused CBT was assessed in a controlled 12-week trial ([Cohen et al. 2007](#)). Although both groups showed significant improvement in symptoms of PTSD, there was no significant advantage from adding sertraline rather than placebo to CBT.

# Citalopram

Eight adolescents with PTSD received citalopram in a fixed daily dosage of 20 mg in a 12-week open-label study ([Seedat et al. 2001](#)). Core PTSD symptoms of reexperiencing, avoidance, and hyperarousal showed statistically significant improvement at week 12, with a 38% reduction in total score on the Clinician-Administered PTSD Scale—Child and Adolescent Version (CAPS-CA). Citalopram was well tolerated, and the most common side effects were increased sweating, nausea, headache, and tiredness.

In a larger 8-week open trial, [Seedat et al. \(2002\)](#) treated 24 children and adolescents with citalopram (dosage range=20–40 mg/day; mean daily dosage=20 mg). Both the children and the adolescents had a significant reduction in

CAPS-CA scores at endpoint. Common side effects of citalopram were drowsiness, headache, nausea, and increased sweating.

## Guanfacine

The effectiveness of guanfacine extended release (GXR) was assessed in an 8-week open-label trial for 19 youths (ages 6–18 years) with current traumatic stress symptoms ([Connor et al. 2013](#)). GXR dosages ranged from 1 to 4 mg/day. On parent report, symptom clusters of reexperiencing, avoidance, and overarousal significantly improved.

## Clonidine

Seven preschool children (ages 3–6 years) with a diagnosis of PTSD received open treatment with clonidine at a dosage range of 0.05–0.15 mg/day ([Harmon and Riggs 1996](#)). To decrease sedation, oral clonidine was subsequently converted to a clonidine patch. The majority of children showed at least moderate improvements in hyperarousal, hypervigilance, insomnia, nightmares, and mood lability.

## Carbamazepine

Twenty-eight children and adolescents (ages 8–17 years) with a diagnosis of PTSD received carbamazepine (dosage range=300–1,200 mg/day) for an average of 35 days. Twenty-two patients (78%) became asymptomatic, and the

remaining six patients were significantly improved during the course of treatment ([Looff et al. 1995](#)).

## Propranolol

The efficacy of propranolol initiated within 12 hours after emergency department admission in preventing PTSD in 29 injured youths was assessed in a 10-day double-blind, placebo-controlled trial ([Nugent et al. 2010](#)). There was no significant difference between the propranolol and placebo groups on PTSD symptoms at 6 weeks.

Eleven children (ages 6–12 years) with a diagnosis of PTSD participated in an off-on-off medication design of 4 weeks of propranolol treatment ([Famularo et al. 1988](#)). Propranolol was initiated at 0.8 mg/kg/day and titrated to a maximum of 2.5 mg/kg/day. A significant improvement in PTSD symptoms was found during the treatment period. Side effects included sedation and mildly lowered blood pressure and pulse.

## Prazosin

In case studies ([Oluwabusi et al. 2012](#); [Strawn and Keeshin 2011](#); [Strawn et al. 2009](#)), prazosin 1–3 mg/day was reported to decrease symptoms of PTSD in children and adolescents.

## D-Cycloserine

In a controlled trial, 57 youths (ages 7–18 years) with PTSD were randomly assigned to receive D-cycloserine and CBT

or placebo and CBT ([Scheeringa and Weems 2014](#)). Although both groups had significant reductions in PTSD symptoms, there was no significant difference between the groups.

## Risperidone

In case reports and a small open-label trial, risperidone has shown some benefit in reducing symptoms of PTSD in children and adolescents ([Horrigan and Barnhill 1997](#); [Keeshin and Strawn 2009](#); [Meighen et al. 2007](#)).

## Quetiapine

In a case series, six adolescents with PTSD reported improvement in symptoms after 6 weeks of low-dosage (50–200 mg/day) quetiapine ([Stathis et al. 2005](#)).

## Clinical Recommendations for Posttraumatic Stress Disorder

For childhood trauma- and stressor-related disorders, SSRIs are the first-line treatment ([Reinblatt and Walkup 2005](#)). Other possible medications for PTSD are  $\alpha$ - and  $\beta$ -adrenergic blocking agents, non-SSRI antidepressants, and mood-stabilizing agents ([Cohen et al. 2010](#)).

---

## Attention-Deficit/Hyperactivity Disorder

---

The prevalence of ADHD in children and adolescents is estimated to range from 5% to 12%, whereas about 4% of adults in the general population meet criteria for ADHD ([Kessler et al. 2006](#)). In addition to demonstrating the core behavioral features of inattention, hyperactivity, and impulsivity, children with ADHD often have significant impairment in social and academic functioning ([Barkley 2005](#)). Of all of the childhood psychiatric disorders, ADHD has the greatest number of pharmacological treatment studies.

## Psychostimulants

The classes of psychostimulants include methylphenidate, dexamethylphenidate, dextroamphetamine, mixed amphetamine salts, and L-lysine-D-amphetamine (lisdexamfetamine). By the 1980s, there were already hundreds of randomized controlled trials showing the efficacy of stimulants in the treatment of ADHD in school-age children ([Greenhill et al. 1999](#)). [Arnold \(2000\)](#) reviewed studies in which subjects underwent a trial of both amphetamine and methylphenidate. This review suggested that approximately 41% of subjects with ADHD responded equally to methylphenidate and amphetamine, whereas 44% responded preferentially to one of the classes of stimulants. This finding suggests that the initial response rate to stimulants may be as high as 85% if both stimulants are tried (in contrast to the finding of 65%–75% response when only one stimulant is tried). In contrast, placebo response rates in stimulant trials are rarely above 20%–30%, making the effect size of the stimulants (0.8–1.0) one

of the largest among all the psychotropics. At present, however, no method is available to predict which stimulant will produce the best response in a given patient. The past decade has seen the emergence of the long-acting stimulants; studies of these agents have been the focus of major reviews ([Biederman and Spencer 2008](#); [Pliszka and AACAP Work Group on Quality Issues 2007](#)).

Initial research with stimulants was carried out in school-age children, but more recent controlled trials of stimulants have focused on adolescents ([Spencer et al. 2006b](#); [Wilens et al. 2006a](#)) and adults ([Biederman et al. 2006a](#); [Weisler et al. 2006](#)). These studies show that older individuals' rates of response to stimulants are similar to those of children, with adequate response for most subjects being obtained with 70–100 mg/day of methylphenidate or 40–60 mg/day of amphetamine.

Preschoolers with ADHD have also been the focus of investigation. In the NIMH Preschool ADHD Treatment Study (PATs), 183 children (ages 3–5 years) underwent an open-label trial of methylphenidate, with 165 of these subjects subsequently randomly assigned to a double-blind, placebo-controlled crossover trial of methylphenidate lasting 6 weeks ([Greenhill et al. 2006](#); [Wigal et al. 2006](#)). The mean optimal dosage of methylphenidate was found to be  $0.7 \pm 0.4$  mg/kg/day, which is lower than the mean of 1.0 mg/kg/day found to be optimal in school-age children. Eleven percent of subjects discontinued methylphenidate because of adverse events. Compared with school-age children, the preschool group showed a higher rate of emotional adverse events, including crabbiness, irritability, and proneness to crying. The conclusion was that the dosage of methylphenidate (or any stimulant) should be

titrated more conservatively in preschoolers than in school-age patients, and lower mean dosages may be effective.

The appendix at the end of this chapter shows the recommended dosage ranges for these agents. The appendix also discusses adverse events, particularly growth suppression, that occur with psychostimulants.

## Atomoxetine

Atomoxetine is a noradrenergic reuptake inhibitor that has indirect effects on dopamine reuptake in the cortex but not in the striatum ([Bymaster et al. 2002](#)). Numerous double-blind, placebo-controlled trials have demonstrated the medication's efficacy in the treatment of ADHD in children, adolescents, and adults ([Michelson et al. 2001, 2002, 2003](#)). Given its pharmacokinetic half-life of 5 hours, it is generally dosed twice a day. Although open trials comparing methylphenidate with atomoxetine showed the two agents to have similar efficacy ([Kratochvil et al. 2002](#)), double-blind, placebo-controlled trials comparing atomoxetine with amphetamine ([Biederman et al. 2006b](#); [Wigal et al. 2005](#)) and methylphenidate ([Newcorn et al. 2008](#)) have shown the stimulants to be more efficacious.

Atomoxetine is effective in treating ADHD in patients with comorbid tics and may also reduce tics ([Allen et al. 2005](#)). It is also useful in children with ADHD who have comorbid anxiety, showing effectiveness in treating anxiety and inattention ([Sumner et al. 2005](#)). Atomoxetine is well tolerated in long-term use. In a global multicenter study, 416 children and adolescents who responded to an initial 12-week open-label period of treatment with atomoxetine were randomly assigned to continued atomoxetine

treatment or placebo for 9 months under double-blind conditions. Relapse (defined as a return to 90% of baseline symptom severity) occurred significantly less often with atomoxetine (22.3%) than with placebo (37.9%) ([Michelson et al. 2001](#)). Data from 13 (6 double-blind, 7 open-label) atomoxetine studies were pooled for youths (ages 12–18 years) with ADHD ([Wilens et al. 2006b](#)). Of the 601 atomoxetine-treated subjects in this meta-analysis, 537 (89.4%) completed 3 months of acute treatment. At the time of the article's publication, 259 subjects (48.4%) were continuing atomoxetine treatment; 219 of these subjects had completed at least 2 years of treatment. Symptoms remained improved for up to 24 months without dosage escalation. During the 2-year treatment period, 99 subjects (16.5%) discontinued treatment due to lack of effectiveness, and 31 subjects (5.2%) discontinued treatment due to adverse events. No clinically significant abnormalities in height, weight, blood pressure, pulse, mean laboratory values, or electrocardiography parameters were found.

## Clonidine

A review of the literature from 1980 to 1999 found 39 studies regarding the use of clonidine for symptoms of childhood ADHD, and 11 of these studies had sufficient data to be included in a meta-analysis ([Connor et al. 1999](#)). Of the 150 subjects in these studies, 42 received clonidine for ADHD, and the others received clonidine for ADHD comorbid with tic disorders ( $n=67$ ), developmental disorders ( $n=15$ ), or conduct disorders ( $n=26$ ). The mean daily dosage of clonidine was 0.18 mg, and the average length of treatment was 10.9 weeks. Clonidine showed a

moderate effect size of 0.58 on symptoms of ADHD, which is smaller than the effect size (0.82) reported for stimulant treatment of ADHD ([Swanson et al. 1995b](#)).

An extended-release (ER) form of clonidine was more recently developed, and this formulation was evaluated in an 8-week double-blind, placebo-controlled trial ([Jain et al. 2011](#)) in which patients ( $N=236$ ) were randomly assigned to receive clonidine ER 0.2 mg/day, clonidine ER 0.4 mg/day, or placebo. Improvement in ADHD symptoms was significantly greater in the clonidine groups relative to the placebo group, with this difference apparent at week 2 and greatest at week 5. Somnolence was the most common side effect, and the rate of withdrawal due to adverse events was higher in the clonidine ER 0.4-mg/day group than in the other groups. There were no serious adverse events, and bradycardia was the most common cardiovascular side effect.

Clonidine ER has been added to stimulant medication in an effort to improve the initial stimulant response in the treatment of ADHD ([Kollins et al. 2011](#)). Children and adolescents with ADHD who had an inadequate response to their initial stimulant regimen ( $n=198$ ) were randomized to receive placebo or clonidine extended release added to their stable stimulant dosage for 8 weeks. Clonidine ER was flexibly dosed. At weeks 4 and 5, of the patients within the group receiving clonidine ER plus stimulant, 3%, 15%, 68%, and 14% received clonidine ER 0.1 mg/day, 0.2 mg/day, 0.3 mg/day, and 0.4 mg/day, respectively. Reduction in ADHD Rating Scale IV (ADHD-RS-IV) scores was greater for the group receiving clonidine ER than for the group receiving placebo in weeks 2–7 but not at week 8. Oddly, although addition of clonidine ER to amphetamine led to significantly

greater improvement, addition to methylphenidate did not. No serious adverse events were reported.

## Guanfacine

In a study by [Hunt et al. \(1995\)](#), 13 children and adolescents with ADHD received guanfacine (mean daily dosage=3.2 mg) for 1 month. Significant improvements in hyperactivity and inattention were found. In an 8-week double-blind, placebo-controlled trial, 34 children and adolescents (ages 7–14 years) with ADHD and tic disorder were randomly assigned to receive guanfacine (dosage range=1.5–3.0 mg/day) or placebo ([Scahill et al. 2001](#)). A 37% improvement in ADHD symptoms was reported for children treated with guanfacine, compared with an 8% improvement for children who received placebo. The most common side effects of guanfacine were sedation and dry mouth. There were no significant changes in pulse or blood pressure with guanfacine treatment.

An extended-release formulation of guanfacine (GXR) is also used for the treatment of ADHD ([Biederman et al. 2008](#); [Sallee et al. 2009](#)). In a double-blind, placebo-controlled Phase III multicenter trial ([Melmed et al. 2006](#)), children and adolescents ages 6–17 years were randomly assigned to placebo or 2 mg, 3 mg, or 4 mg/day of GXR. All three dosages of GXR were superior to placebo in reducing symptoms of ADHD. The most commonly reported side effects of GXR were headache, somnolence, and fatigue. No serious adverse events were reported. In healthy young adults (ages 19–24 years), abrupt discontinuation of 4 mg/day of GXR did not lead to increases in blood pressure

or electrocardiogram (ECG) abnormalities ([Kisicki et al. 2006](#)).

GXR has also been assessed as add-on therapy when children with ADHD have only a partial response to stimulants ([Wilens et al. 2012](#)). In a 9-week double-blind, placebo-controlled dosage optimization study, patients ( $N=461$ ) continued their stable dosage of psychostimulant given in the morning and were randomized to receive GXR in the morning (GXR AM), GXR in the evening (GXR PM), or placebo. At endpoint, compared with the group receiving placebo plus psychostimulant, each guanfacine treatment group showed significantly greater improvement from baseline on ADHD-RS-IV total scores. Results did not differ between the GXR AM and GXR PM groups in either efficacy or adverse events. There were no serious or unexpected adverse events.

## Clinical Recommendations for Attention-Deficit/Hyperactivity Disorder

Based on the strength of clinical trial data, stimulants should be regarded as the first line for treatment of ADHD, and generally a different stimulant class should be used if the first stimulant prescribed has failed. Either atomoxetine or guanfacine is an appropriate second-line agent. Stimulants have been combined with atomoxetine in an open trial, with results suggesting that the two agents are superior to atomoxetine alone ([Wilens et al. 2009](#)). Placebo-controlled studies have shown that the addition of either guanfacine ([Wilens et al. 2012](#)) or clonidine ([Kollins et al.](#)

[2011](#)) can further reduce symptoms of ADHD after a partial response to psychostimulants. Thus,  $\alpha_2$ -adrenergic receptor agonists are increasingly used in this adjunctive role.

The stages of pharmacological treatment of ADHD can be summarized as follows:

- Stage 1: Psychostimulant
- Stage 2: Alternative psychostimulant
- Stage 3: Atomoxetine or  $\alpha_2$  agonist
- Stage 4: Combination of  $\alpha_2$  agonist or atomoxetine with stimulant

---

## Disruptive Behavior Disorders and Aggression

---

Oppositional defiant disorder (ODD) and conduct disorder (CD) are highly comorbid with ADHD, particularly in younger children ([Pliszka et al. 1999](#)). ODD and CD are *syndromes*, whereas aggression is a *symptom*. Although many children and adolescents with CD are aggressive, a child can meet criteria for CD without being aggressive. Also, aggression may present as a problematic symptom in children with depression, psychosis, or bipolar disorder without the child meeting criteria for CD. Thus, the clinician must be clear whether the target of treatment is the syndrome of ODD or CD or the symptom of aggression, because studies have addressed the problems separately. Treatments for ADHD have been used to target ODD and CD, whereas mood stabilizers and antipsychotics have been used in patients with severe aggressive outbursts, regardless of diagnosis ([Pappadopulos et al. 2006](#)).

# Oppositional Defiant Disorder and Conduct Disorder

## Psychostimulants

In a 5-week double-blind, placebo-controlled trial of methylphenidate in 84 youths (ages 6–15 years) with CD (with and without ADHD), ratings of antisocial behaviors specific to CD were significantly reduced by methylphenidate treatment (up to 60 mg/day) ([Klein et al. 1997](#)). The severity of the ADHD did not affect the response of CD symptoms in the stimulant study. Since that study, multiple double-blind, placebo-controlled trials have shown that ODD responds to stimulant medication, yielding an effect size similar to that for the ADHD symptoms ([Spencer et al. 2006a](#)).

## Atomoxetine

Children and adolescents (ages 8–18 years) with ADHD were treated for approximately 8 weeks with placebo or atomoxetine under randomized, double-blind conditions. Of the 293 subjects, 39% were diagnosed with comorbid ODD and 61% were not ([Newcorn et al. 2005](#)). Treatment group differences and differences between patients with and without comorbid ODD were examined post hoc for changes on numerous clinical measures. Treatment response was similar in youth with and without ODD, although the comorbid group may require higher dosages to achieve response than those with ADHD alone.

In general, a child with ODD or CD should be treated with a stimulant or atomoxetine before proceeding to the use of other psychotropic agents. The use of more potent agents

(mood stabilizers, antipsychotics) is generally reserved for those with severe aggression, and then only after a behavioral treatment has failed.

## Aggression

### Psychostimulants

In a meta-analysis of the literature from 1970 to 2001 that examined 28 studies to determine the effect size for stimulants on overt and covert aggression-related behaviors in children with ADHD, it was found that the mean effect size for aggressive behaviors was similar to that for core behaviors of ADHD ([Connor et al. 2002](#)).

### Risperidone

A significant body of research has accumulated showing the effectiveness of risperidone in the treatment of aggression, although most of these studies involve patients with subaverage intelligence ([Snyder et al. 2002](#)); 80% of subjects had comorbid ADHD. Risperidone dosages ranged from 0.02 to 0.06 mg/kg/day. The risperidone-treated subjects showed a significant ( $P<0.001$ ) reduction (47.3%) in conduct problems compared with placebo-treated subjects (20.9%). The effect of risperidone was unaffected by diagnosis, presence versus absence of ADHD, psychostimulant use, and IQ status. Risperidone produced no changes in the cognitive variables, and the most common side effects were somnolence, headache, appetite increase, and dyspepsia. Somnolence did not predict response of aggressive symptoms. Side effects related to EPS were reported in 7 (13.2%) and 3 (5.3%) of the

subjects in the risperidone and placebo groups, respectively ( $P=0.245$ ).

Other double-blind, placebo-controlled trials of risperidone in children and adolescents with disruptive behavior disorders (and subaverage IQ) have yielded similar results, with no negative trials reported ([Aman et al. 2002](#); [Buitelaar et al. 2001](#); [LeBlanc et al. 2005](#)). Weight gain was a significant side effect in these studies, but there has not been evidence of adverse neuropsychological effects ([Günther et al. 2006](#)). Addition of risperidone to a stimulant does not appear to increase rates of side effects and enhances treatment of hyperactivity ([Aman et al. 2004](#)). Indeed, adding risperidone to a stimulant to control aggression has become a common practice, although a controlled study showed that aggression was equally reduced when either placebo or risperidone was added to psychostimulant medication ([Armenteros et al. 2007](#)). The sample in this study was small ( $N=25$ ), but the study should caution clinicians that aggression can respond to psychosocial events, such as the expectations of a study.

[Pandina et al. \(2006\)](#) wrote a full review of all studies of risperidone in the treatment of childhood aggression. This review pooled adverse-event data from these studies, showing the most common side effects of risperidone to be somnolence (33%), weight gain (20%), hyperprolactinemia (10.2%), and fatigue (10%). In the pooled studies, there was an excess mean weight gain (over normal growth) of  $6.0 \pm 7$  kg after 35–43 weeks of treatment. Of the 688 patients, 651 were free of dyskinetic movements at baseline, and only 1 patient developed new dyskinetic movements during the follow-up period (these symptoms resolved even though risperidone was continued). There was no worsening of dyskinetic movements in those patients with such

preexisting symptoms. Rates of EPS were low throughout the long-term follow-up period. It should be noted that the dosages of risperidone used in these studies were quite low (1–2 mg/day); thus, these results may not apply to dosages in the 6-mg/day range.

[Aman et al. \(2014\)](#) tested the efficacy of adding risperidone to concurrent psychostimulant treatment and parent training (PT) in behavior management in children with ADHD and severe comorbid aggression. Children ages 6–12 years (mean age 8.89 years) with severe physical aggression were randomly assigned to a 9-week trial of PT, stimulant, and placebo (basic treatment;  $n=84$ ) or of PT, stimulant, and risperidone (augmented treatment;  $n=84$ ). Children received a psychostimulant for 3 weeks, titrated for optimal effect, while parents received PT. If there was room for improvement at the end of week 3, placebo or risperidone was added for an additional 3 weeks. Both groups showed substantial reductions in aggressive behavior during the first 3 weeks of stimulant plus PT treatment. In the second phase, the risperidone group showed significantly greater reduction in rating scale measures of aggressive behavior, but CGI-I scores did not discriminate the groups. Adverse events were as expected, with the risperidone group experiencing greater weight gain and increases in serum lipid and prolactin levels than the placebo group. The study clearly showed the need to adequately treat ADHD in the aggressive child before prescribing second-generation antipsychotics.

## **Other Atypical Antipsychotics**

There have been only small open trials and case reports of the use of quetiapine, aripiprazole, olanzapine, and ziprasidone in the treatment of aggression ([Findling et al.](#)

2006; Hazaray et al. 2004; Khan and Mican 2006; Rugino and Janvier 2005; Staller 2004; Stephens et al. 2004; Valicenti-McDermott and Demb 2006). In most of these studies, children had primary psychiatric diagnoses other than ODD or CD, such as mood disorders or developmental disorders.

## Lithium

The efficacy of lithium in the treatment of CD in youth has been demonstrated in three double-blind, placebo-controlled studies. Haloperidol, lithium, and placebo were compared in a double-blind, randomized trial in 61 hospitalized children (ages 5–12 years) with aggression and CD (Campbell et al. 1984). The optimal dosages of haloperidol ranged from 1 to 6 mg/day; the optimal dosages of lithium ranged from 500 to 2,000 mg/day. Both haloperidol and lithium were found to be significantly superior to placebo in reducing aggression. However, there were more adverse effects associated with haloperidol than with lithium, including excessive sedation, acute dystonic reaction, and drooling. Stomachache, headache, and tremor were more common with lithium than with haloperidol.

In a subsequent study, Campbell et al. (1995) conducted a 6-week double-blind, placebo-controlled trial of lithium treatment for 50 hospitalized children (ages 5–12 years) with aggression and CD. The mean optimal daily dosage of lithium was 1,248 mg, and the mean serum level was 1.12 mEq/L. Lithium was significantly superior to placebo in reducing aggression. The most common lithium side effects were stomachache, nausea, vomiting, headache, tremor, and urinary frequency.

Eighty-six inpatients (ages 10–17 years) with CD were randomly assigned to treatment with lithium (mean daily dosage=1,425 mg; mean serum level=1.07 mmol/L) or placebo in a 4-week double-blind trial. Aggression ratings decreased significantly for the group treated with lithium, compared with the group treated with placebo. More than 50% of patients in the lithium group experienced nausea, vomiting, and urinary frequency ([Malone et al. 2000](#)).

In contrast, [Rifkin et al. \(1997\)](#) found no significant differences between lithium and placebo in aggression ratings in a 2-week double-blind study of 33 inpatients with CD. The short duration of treatment may have accounted for the lack of efficacy, suggesting that a 4- to 6-week trial is necessary to show response.

Severe mood dysregulation, referred to in DSM-5 as disruptive mood dysregulation disorder, is often characterized by severe aggressive outbursts. [Dickstein et al. \(2009\)](#) studied the effect of lithium in youths (ages 7–17 years) with severe mood dysregulation who were tapered off their medications. Those who continued to have significant mood dysregulation after a 2-week single-blind placebo run-in were randomized to a 6-week double-blind trial of either lithium ( $n=14$ ) or placebo ( $n=11$ ). Interestingly, 20 of 45 youths (45%) with severe mood dysregulation were not randomized due to significant clinical improvement during the placebo run-in. Among randomized patients, there were no significant between-group differences in any clinical measures. The placebo group showed no improvement at all (a true negative trial), with no evidence that an increase in sample size would have changed the results.

## **Divalproex**

Twenty outpatient children and adolescents (ages 10–18 years) with CD or ODD were randomly assigned to divalproex (dosage range=750–1,500 mg/day; mean blood level=82 µg/mL) or placebo in a 6-week double-blind, placebo-controlled crossover study. Of the 15 patients who completed both phases, 12 (80%) had a statistically significant superior response to divalproex. Increased appetite was the only significant side effect ([Donovan et al. 2000](#)). [Steiner et al. \(2003\)](#) randomly assigned 71 adolescents with CD in a residential facility for juvenile offenders to two groups, which received either a therapeutic dosage or a low dosage of divalproex for 7 weeks; both subjects and outcome raters were blind to treatment status. Reduction in aggression severity ( $P=0.02$ ), improvement in impulse control ( $P<0.05$ ), and global improvement ( $P=0.0008$ ) were greater in the group with therapeutic divalproex levels than in the low-dosage condition. As reported in another article from the same study, serum level and “immature defenses” (as assessed by the Weinberger Adjustment Inventory) predicted response to divalproex, but psychiatric comorbidity did not ([Saxena et al. 2005](#)).

[Blader et al. \(2009\)](#) treated 74 children with ADHD and aggression with open stimulant treatment during a lead-in phase that averaged 5 weeks. Children whose aggressive behavior persisted at the conclusion of the lead-in phase ( $n=30$ ) were randomly assigned to receive double-blind, flexibly dosed divalproex or a placebo adjunctive to stimulant for 8 weeks. Families received weekly behavioral therapy throughout the trial. A significantly higher proportion of the children randomly assigned to divalproex met remission criteria (8 of 14; 57%) than of those randomly assigned to placebo (2 of 13; 15%).

## Clonidine

Clonidine has often been combined with stimulants to treat comorbid aggression in children with ADHD. In a 2-month randomized comparison of clonidine, methylphenidate, and clonidine combined with methylphenidate in the treatment of 24 children and adolescents (ages 6–16 years) with ADHD and CD or ODD, it was found that all three treatment groups showed significant improvement in oppositional and CD symptoms ([Connor et al. 2000](#)). No significant ECG changes were noted.

Children (ages 6–14 years) with ADHD currently taking methylphenidate were randomly assigned to receive clonidine syrup 0.10–0.20 mg/day ( $n=37$ ) or placebo ( $n=29$ ) for 6 weeks ([Hazell and Stuart 2003](#)). Analysis showed that significantly more clonidine-treated children than control subjects were responders on the Conduct subscale (21 of 37 vs. 6 of 29;  $P<0.01$ ) of the parent-report Conners Behavior Checklist, but not on the Hyperactive Index subscale (13 of 37 vs. 5 of 29). Compared with placebo, clonidine was associated with a greater reduction in systolic blood pressure measured standing and with transient sedation and dizziness. Clonidine-treated individuals had a greater reduction in a number of unwanted effects associated with psychostimulant treatment compared with placebo. The findings supported the use of clonidine in combination with psychostimulant medication to reduce conduct symptoms associated with ADHD.

## Clinical Recommendations for Disruptive Behavior Disorders and

# Aggression

The Center for the Advancement of Children's Mental Health at Columbia University joined with the New York State Office of Mental Health to develop guidelines for treatment of aggression, which led to the Treatment Recommendations for the Use of Antipsychotics for Aggressive Youth (TRAAY; [Pappadopulos et al. 2003](#); [Schur et al. 2003](#)). These recommendations call first for a thorough psychiatric evaluation of the child with severe aggression. Next, a psychosocial intervention should be used first when the aggression is the primary problem, such as in ODD, CD, or intermittent explosive disorder. The clinician should then treat any primary condition, such as ADHD, psychosis, or mood disorder that may be causing or contributing to the aggression. If the aggression does not respond to these steps, then an atypical antipsychotic should be used. Different atypical antipsychotics should be tried as monotherapy before moving to polypharmacy (e.g., adding a classic mood stabilizer such as lithium or divalproex to the antipsychotic). Monitoring of weight and laboratory measures of glucose, cholesterol, and triglycerides is mandatory ([Correll and Carlson 2006](#)).

$\alpha_2$ -Adrenergic receptor agonists may be used in children with milder aggression or temper outbursts because the effect size of these medications on aggression is more modest ([Hazell and Stuart 2003](#)).

---

## Tourette Syndrome

---

The prevalence of Tourette syndrome is estimated to be 0.7% in children ([Comings et al. 1990](#)). Tourette syndrome is characterized by multiple motor tics and by one or more vocal tics that occur frequently for longer than 1 year. More commonly children suffer from chronic motor or vocal tics, but treatment is the same as for Tourette syndrome. A meta-analysis has been performed examining the effects of  $\alpha_2$ -adrenergic receptor agonists and antipsychotics in the pharmacological treatment of tics ([Weisman et al. 2013](#)).

## Alpha-2-Adrenergic Receptor Agonists

[Weisman et al. \(2013\)](#) identified six placebo-controlled studies examining the effect of clonidine ([Du et al. 2008](#); [Leckman et al. 1991](#); [Singer et al. 1995](#); [Tourette's Syndrome Study Group 2002](#)) or guanfacine ([Cummings et al. 2002](#); [Scahill et al. 2001](#)) in patients with tics. A meta-analysis demonstrated a significant effect of an  $\alpha_2$  agonist relative to placebo, with a standardized mean difference of 0.31 (95% confidence interval [CI], 0.15-0.48). This is a fairly modest effect. Of note, the analysis showed that clonidine had a significantly larger effect against tics when patients had comorbid ADHD than when patients did not have ADHD.

## Antipsychotics

[Weisman et al. \(2013\)](#) reviewed five placebo-controlled studies of haloperidol and pimozide ([Sallee et al. 1997](#); [Shapiro et al. 1989](#)), ziprasidone ([Sallee et al. 2000](#)), and

risperidone ([Dion et al. 2002](#); [Scahill et al. 2003](#)). Two studies directly compared haloperidol and risperidone without a placebo control ([Bruggeman et al. 2001](#); [Gilbert et al. 2004](#)), one study compared risperidone and clonidine ([Gaffney et al. 2002](#)), and one study compared haloperidol and the clonidine patch ([Kang et al. 2009](#)). However, the [Kang et al. \(2009\)](#) study, unlike the others, was not blinded. In the meta-analysis, all antipsychotics were superior to placebo, with a standardized mean difference of 0.61 (95% CI, 0.36-0.86). There was no difference between the various antipsychotic agents with regard to their efficacy for reducing tics. [Gaffney et al. \(2002\)](#) found clonidine and risperidone to be equivalent in efficacy. Studies of aripiprazole were not included in the [Weisman et al. \(2013\)](#) meta-analysis.

[Murphy et al. \(2005\)](#) reported six cases of children and adolescents (age range= 8-19 years; mean age=12.1 years) who had comorbid tic disorder and OCD and were treated with aripiprazole (mean dosage=11.7 mg/day; range=5-20 mg/day) for 12 weeks. The subjects experienced a mean reduction of 56% in the severity of their tics as assessed by the Yale Global Tic Severity Scale (YGTSS). Similarly, [Yoo et al. \(2006\)](#) treated 15 children and adolescents who had tic disorder with aripiprazole (mean dosage=10.89 mg/day; range=12.5-15 mg/day) and reported a mean reduction of 40% in YGTSS scores; side effects were minimal. Two subjects experienced nausea, one experienced weight gain, and one experienced sedation. The sedation responded to dosage reduction.

In a case series, 11 consecutive patients with Tourette syndrome (mean age=7 years; age range=7-50 years) were treated with aripiprazole; the symptoms of the majority of these patients had been refractory to previous

treatments with other antipsychotics ([Davies et al. 2006](#)). Ten of the 11 patients who were treated with aripiprazole improved, although to variable degrees. In the majority of patients, response was sustained with aripiprazole dosages ranging from 10 to 20 mg/day. Side effects were mild and transient.

[Zheng et al. \(2016\)](#) reviewed six studies of the treatment of tics with aripiprazole. This study included two randomized controlled trials, but in these studies aripiprazole was compared only with tiapride, an antipsychotic not available in the United States. The other four were open trials. The review found aripiprazole to be well tolerated and effective in reducing tics relative to baseline levels.

## Clinical Recommendations for Tourette Syndrome

If a tic is not severe or socially impairing, observation may be in order because tics typically wax and wane; in general, tics improve over time ([Leckman 2002](#)). Often, psychosocial treatment such as habit reversal training is highly effective at reducing tics ([Piacentini and Chang 2006](#)). If conservative treatment fails, use of an  $\alpha_2$  agonist would be desirable, due to the risk of weight gain and dyslipidemia with atypical antipsychotics. The atypical antipsychotics are preferred to typical antipsychotics because the latter have lower efficacy and a higher risk of tardive dyskinesia. Haloperidol and pimozide should be used only as a last resort when several atypical agents have failed.

In children with comorbid ADHD, a stimulant can be used, but a nonstimulant is indicated if the stimulant exacerbates

tics ([Pliszka et al. 2006a](#)). Stimulants often must be combined with  $\alpha_2$  agonists or antipsychotics to control both the ADHD and the tics ([Pliszka et al. 2006a](#); [Tourette's Syndrome Study Group 2002](#)).

---

## Schizophrenia

---

Cases of schizophrenia in children younger than age 13 years are very rare; however, the prevalence rises in adolescence, with peak onset between ages 15 and 30 years ([McClellan and Werry 2001](#)). The clinical features of the disorder are similar in youth and adults, and the same DSM-5 criteria are used to establish a diagnosis. The outcome of childhood-onset schizophrenia is reported to be poor ([Eggers and Bunk 1997](#)).

## Atypical Antipsychotics

Five atypical antipsychotics have FDA approval for the treatment of schizophrenia in adolescents: olanzapine (for ages  $\geq 13$  years), risperidone ( $\geq 13$  years), aripiprazole ( $\geq 13$  years), quetiapine ( $\geq 13$  years), and paliperidone ER ( $\geq 12$  years). Ziprasidone, asenapine, and clozapine have been studied for treatment of schizophrenia in youth but do not have FDA approval.

### Olanzapine

In a double-blind, placebo-controlled multicenter study of olanzapine (mean dosage=11.1 mg/day) for the treatment of adolescents with schizophrenia ([Kryzhanovskaya et al. 2009](#)), 107 adolescents were randomly assigned to receive

olanzapine ( $n=72$ ) or placebo ( $n=35$ ) for a 6-week trial. Olanzapine-treated adolescents had significant improvements on the Brief Psychiatric Rating Scale for Children (BPRS-C) and on CGI-S scores compared with the placebo group. There was no significant difference in response rate (defined as a  $\geq 30\%$  decrease in BPRS-C and a CGI-S score  $\leq 3$ ) between the olanzapine (37.5%) and placebo (25.7%) groups. Significantly more olanzapine-treated adolescents had high aspartate aminotransferase/serum glutamic oxaloacetic transaminase (AST/SGOT), alanine aminotransferase/serum glutamic pyruvic transaminase (ALT/SGPT), and prolactin levels, as well as low bilirubin levels and hematocrit values, during treatment. There was a significant increase in fasting triglycerides at endpoint in the olanzapine-treated adolescents. Early response at 2 and 3 weeks has been shown to predict ultimate response and remission at week 6 ([Stentebjerg-Olesen et al. 2015](#)).

## Risperidone

Positive findings were reported in a double-blind, placebo-controlled multicenter trial of risperidone in the treatment of adolescents with schizophrenia ([Haas et al. 2007](#)). One hundred sixty adolescents were randomly assigned to risperidone 1–3 mg/day ( $n=55$ ), risperidone 4–6 mg/day ( $n=51$ ), or placebo ( $n=54$ ) for a 6-week trial. Both dosage ranges of risperidone were significantly superior to placebo on the primary efficacy measure, the Positive and Negative Syndrome Scale (PANSS) total change score at endpoint. The most common adverse events in the risperidone 1- to 3-mg/day group were somnolence (24%), agitation (15%), and headache (13%). EPS (16%), dizziness (14%), and hypertonia (14%) were the most common adverse events in

the risperidone 4- to 6-mg/day group. The investigators concluded that the overall risk-benefit ratio favored the lower dosage range of risperidone.

## **Aripiprazole**

In a large double-blind, placebo-controlled multicenter trial of aripiprazole for the treatment of schizophrenia in adolescents ([Findling et al. 2008](#)), 302 adolescents were randomly assigned to receive aripiprazole 10 mg/day, aripiprazole 30 mg/day (after 5- or 11-day titration), or placebo over a 6-week period. Both dosages of aripiprazole showed statistically significant differences from placebo on the PANSS total score at week 6. The most common adverse events associated with aripiprazole were EPS, somnolence, and tremor. Early response to aripiprazole at weeks 2 and 3 has been shown to predict later response and remission ([Correll et al. 2013](#)).

## **Quetiapine**

The efficacy of quetiapine in the treatment of schizophrenia in adolescents was evaluated in a 6-week double-blind, placebo-controlled trial in which subjects ( $N=222$ ) were randomly assigned to quetiapine 400 mg/day, quetiapine 800 mg/day, or placebo ([Findling et al. 2012](#)). Both quetiapine dosages were significantly superior to placebo in reduction of total PANSS scores. The most common adverse events with quetiapine were somnolence, headache, and dizziness. Mean changes in body weight, total cholesterol, and total triglycerides were greater in the quetiapine group than the placebo group.

## **Paliperidone Extended Release**

Paliperidone ER was evaluated in a 6-week double-blind, placebo-controlled trial in 201 adolescents (ages 12–17 years) with schizophrenia ([Singh et al. 2011](#)). Paliperidone ER fixed dosing was weight based; youth weighing 29 kg to less than 51 kg received 1.5 mg, 3 mg, or 6 mg/day, whereas patients weighing at least 51 kg received 1.5 mg, 6 mg, or 12 mg/day. With weight-based treatment, only the medium dosage range (3–6 mg/day) showed significant improvement compared with placebo. The fixed dosages of 3 mg/day, 6 mg/day, and 12 mg/day were also superior to placebo. Somnolence, akathisia, insomnia, headache, and tremor were the most common adverse events in the paliperidone ER group.

The long-term safety of paliperidone ER was evaluated in a 2-year open-label study for 400 adolescents with schizophrenia ([Savitz et al. 2015](#)). The most frequently reported treatment-emergent adverse events were increased weight, headache, insomnia, nasopharyngitis, akathisia, schizophrenia exacerbation, and tremor. There were no clinically significant changes in weight or BMI. Hyperprolactinemia was found in 56% of patients, and 9.3% had prolactin-related adverse events. The most common EPS-related adverse events were parkinsonism (15.5%) and hyperkinesia (13.8%).

## **Ziprasidone**

The efficacy of ziprasidone was evaluated in a 6-week double-blind, placebo-controlled trial for 283 adolescents ages 13–17 years with schizophrenia ([Findling et al. 2013](#)). Ziprasidone was flexibly dosed (40–160 mg/day). There was no significant difference between ziprasidone and placebo on change from baseline to endpoint on the BPRS-Anchored. The most common adverse events in the

ziprasidone group were somnolence and EPS. During the 26-week open-label follow-up, there were no clinically significant changes in metabolic indices and laboratory measures.

## Asenapine

The efficacy of asenapine was assessed in an 8-week double-blind, placebo-controlled trial for adolescents ages 12–17 years with schizophrenia ([Findling et al. 2015a](#)). Asenapine dosing was 2.5 mg bid or 5 mg bid. Asenapine was not significantly superior to placebo on the primary efficacy measure of change from baseline to endpoint on the PANSS total score. Weight gain  $\geq 7\%$ , somnolence, sedation, and hypersomnia were more common in the asenapine group than the placebo group. Adverse events of akathisia, fasting glucose elevation, and EPS were more common in the asenapine 5 mg bid group than the placebo group. Those youth who showed improvement during the acute phase maintained improvement in the 26-week open-label extension.

## Clozapine

A 6-week double-blind, placebo-controlled comparison of clozapine and haloperidol was conducted in 21 children and adolescents (ages 6–18 years) with schizophrenia ([Kumra et al. 1996](#)). Clozapine (mean dosage=176 mg/day; range=25–525 mg/day) was significantly superior to haloperidol (mean dosage=16 mg/day; range=7–27 mg/day) in reducing positive and negative symptoms of schizophrenia. Clozapine improved interpersonal functioning and enabled patients to live in a less restrictive setting. Side effects, however, were significant with

clozapine. One patient had a seizure, and three patients were given anticonvulsants after they became more irritable and aggressive and experienced epileptiform changes on electroencephalogram (EEG). Mild to moderate neutropenia, weight gain, and sinus tachycardia were the other major side effects.

## Comparison of Atypical Antipsychotics

In a 12-week open-label trial, risperidone (mean dosage=1.6 mg/day) was compared with olanzapine (mean dosage=8.2 mg/day) in the treatment of 25 children with schizophrenia ([Mozes et al. 2006](#)). Both treatment groups showed similar significant improvement as measured by PANSS total and subscale scores.

In an 8-week double-blind study, 50 children and adolescents (ages 8–19 years) with psychotic disorders were randomly assigned to receive risperidone (mean dosage=4 mg/day), olanzapine (mean dosage=12.3 mg/day), or haloperidol (mean dosage=5 mg/day) ([Sikich et al. 2004](#)). Eighty-eight percent of patients treated with olanzapine, 74% treated with risperidone, and 53% treated with haloperidol met response criteria (CGI-I scores of much or very much improved and at least a 20% reduction in BPRS-C total score).

Clozapine was compared with olanzapine in an 8-week double-blind randomized trial ([Shaw et al. 2006](#)). Twenty-five youths (ages 7–16 years) with schizophrenia that was resistant to treatment with at least two antipsychotics participated in the trial. Clozapine (mean dosage=327 mg/day) showed significant improvement on all outcome

measures, whereas olanzapine (mean dosage=19.1 mg/day) showed improvement on some outcome measures. Improvement in negative symptoms was significantly greater for the clozapine group.

In an 8-week double-blind trial comparing olanzapine and risperidone against the typical antipsychotic molindone in 116 children and adolescents with early-onset schizophrenia or schizoaffective disorder ([Sikich et al. 2008](#)), no significant differences were observed in rates of response (CGI-I score  $\leq 2$ , and  $\geq 20\%$  reduction in PANSS total score) among the treatment groups (risperidone 46%, olanzapine 34%, and molindone 50%). Significantly greater weight gain occurred with olanzapine and risperidone than with molindone.

A double-blind maintenance study followed this acute controlled trial in children and adolescents with early-onset schizophrenia or schizoaffective disorder ([Findling et al. 2010](#)). Of the 54 youths eligible for the maintenance phase, 14 (26%) completed 44 weeks of treatment. No significant differences were found among olanzapine, risperidone, and molindone in reduction of symptoms or time to discontinuation.

In an 8-week double-blind trial comparing paliperidone ER and aripiprazole in 228 adolescents with schizophrenia ([Savitz et al. 2015](#)), there was no significant difference between the paliperidone ER group and the aripiprazole group on change in PANSS scores from baseline to endpoint. Both medication groups showed improvement in symptoms and functional outcomes.

## Typical Antipsychotics

## Haloperidol

Haloperidol has been compared with placebo and other typical antipsychotics in controlled trials in youth. In a 10-week double-blind, placebo-controlled crossover study, the safety and efficacy of haloperidol were assessed in 12 hospitalized children (ages 5–12 years) with schizophrenia. Haloperidol (optimal dosage range=0.5–3.5 mg/day) was significantly superior to placebo in improving overall clinical functioning and reducing ideas of reference, delusions, and hallucinations. Common side effects were acute dystonic reaction, drowsiness, and dizziness ([Spencer et al. 1992](#)).

Haloperidol and loxapine were compared in a 4-week double-blind, placebo-controlled study of 75 adolescent inpatients with schizophrenia. Both haloperidol and loxapine were significantly superior to placebo, and there was no significant difference in efficacy between the two medications. Response rates (based on CGI-I scores) were 87.5% for loxapine, 70% for haloperidol, and 36.4% for placebo. Common side effects were sedation, EPS, and somnolence ([Pool et al. 1976](#)).

## Thiothixene

Thiothixene was compared with thioridazine in a 6-week single-blind study in 21 adolescent inpatients with schizophrenia. Thiothixene (optimal mean dosage=16.2 mg/day) and thioridazine (optimal mean dosage=178 mg/day) were equally effective in controlling symptoms, although most of the adolescents continued to be quite impaired. Thiothixene was less sedating than thioridazine ([Realmuto et al. 1984](#)). Thiothixene was also compared with trifluoperazine in an 8-week double-blind study of 16

children (ages 8–15 years) with schizophrenia ([Wolpert et al. 1967](#)). The effects of both medications were similar in terms of decreasing avoidance behavior, reducing stereotypic behavior, and increasing peer socialization.

## Clinical Recommendations for Schizophrenia

Both typical and atypical antipsychotics have demonstrated effectiveness in the treatment of schizophrenia in youth, although the sample sizes have been small in the trials of typical antipsychotics. Because fewer EPS and instances of tardive dyskinesia have been reported with atypical antipsychotics, it would be reasonable to initiate treatment with an atypical antipsychotic for a child with schizophrenia. It is important to monitor weight and metabolic parameters for children who receive atypical antipsychotics. Clozapine should be considered for treatment-resistant schizophrenia ([McClellan et al. 2013](#)).

Antipsychotics should be administered at adequate dosages for a period of 6 weeks to assess efficacy. If there is no response or if intolerable side effects occur, a trial of a different antipsychotic should be initiated ([American Academy of Child and Adolescent Psychiatry 2012](#)).

No data are available to guide maintenance treatment. Because the majority of youth will have a second psychotic episode within 5–7 years of stabilization, there is a significant risk of relapse with medication withdrawal ([Kumra 2000](#)). Maintenance treatment should be provided to most youth with schizophrenia to improve functioning and prevent relapse ([American Academy of Child and Adolescent Psychiatry 2012](#)). The aim is to use the lowest

effective dosage of medication to reduce the risk of adverse events. For those youth with prolonged remission, it may be possible to discontinue medication, but long-term monitoring will be necessary because of possible reemergence of psychotic symptoms.

---

## Autism Spectrum Disorder

---

Autism spectrum disorder is a new DSM-5 disorder that encompasses the previous DSM-IV ([American Psychiatric Association 1994](#)) categories of autistic disorder (autism), Asperger's disorder, and pervasive developmental disorder not otherwise specified. Symptoms of autism spectrum disorder represent a continuum of mild to severe impairments in two core domains: 1) deficits in social communication and social interaction and 2) restricted repetitive patterns of behavior, interests, and activities ([American Psychiatric Association 2013](#)). Associated behavioral features include hyperactivity, stereotypies, attentional problems, self-injurious behavior, aggression, mood lability, anxiety, obsessions, and compulsions. Autism spectrum disorder is estimated to have a prevalence of up to 18.7 per 10,000 population ([Howlin 2000](#)). The majority of children with the disorder will continue to have significant social and communication impairments throughout adulthood ([Buitelaar and Willemsen-Swinkels 2000](#)).

## Atypical Antipsychotics

For the treatment of irritability associated with autism spectrum disorder, the FDA has approved risperidone (for patients  $\geq 5$  years old) and aripiprazole ( $\geq 6$  years old). Olanzapine, quetiapine, and ziprasidone have been studied for autism spectrum disorders but do not have FDA approval for use in youth.

## Risperidone

One hundred one children (ages 5–17 years) with DSM-IV-defined autistic disorder participated in an 8-week double-blind, placebo-controlled trial of risperidone (dosage range=0.5–3.5 mg/day; mean dosage=1.8 mg/day) ([McCracken et al. 2002](#)). A significantly greater positive response (defined as a 25% decrease on the irritability subscale of the Aberrant Behavior Checklist [ABC] and a rating of much or very much improved on the CGI-I) was found for the risperidone group (69%) than the placebo group (12%). Adverse events of increased appetite, fatigue, drowsiness, dizziness, and drooling were more common in the risperidone group than in the placebo group. Mean weight gain was 2.7 kg in the risperidone group and 0.8 kg in the placebo group. An 18-month follow-up showed that the majority of subjects who responded to risperidone during intermediate-length treatment continued to show improvement ([McDougle et al. 2005](#)).

In a 24-month follow-up of 84 of these youths, there was continued improvement in maladaptive behavior from baseline ([Aman et al. 2015](#)). Social skills improved and irritability decreased for those youths who were taking risperidone at follow-up. Risperidone treatment was associated with enuresis, excessive appetite, and weight gain.

In an 8-week double-blind, placebo-controlled trial, 79 children (ages 5-12 years) with a DSM-IV diagnosis of autistic or other pervasive developmental disorder were randomly assigned to receive either placebo or risperidone (mean dosage=1.5 mg/day). Risperidone-treated patients exhibited a 64% improvement over baseline irritability, compared with a 30.7% improvement in subjects receiving placebo ([Shea et al. 2004](#)).

In a 6-month placebo-controlled study of 40 children (ages 2-9 years) with autism, risperidone (1 mg/day) decreased aggressiveness, hyperactivity, and irritability and improved social responsiveness and nonverbal communication. Appetite increase, weight gain, sedation, and transient dyskinesias were reported in the risperidone-treated children ([Nagaraj et al. 2006](#)).

The long-term effects of risperidone were assessed in youths (ages 5-17 years) with autism spectrum disorder ([Troost et al. 2005](#)). Twenty-four youths received risperidone for 6 months, followed by a double-blind discontinuation to placebo or continued risperidone. Risperidone was superior to placebo in preventing relapse, with relapse rates of 25% and 75%, respectively.

In a double-blind, placebo-controlled risperidone dosing study for 96 youths (ages 5-17 years), high-dosage risperidone (1.25 mg/day for youths weighing 20 to <45 kg; 1.75 mg/day for youths weighing  $\geq$ 45 kg) was significantly superior to placebo in baseline-to-endpoint change in score on the ABC Irritability subscale ([Kent et al. 2013b](#)). There was no significant difference, however, between scores of patients given low-dosage risperidone (0.125 mg/day for youths weighing 20 to <45 kg; 0.175 mg/day for youths weighing  $\geq$ 45 kg) and scores of patients given placebo. In an open-label extension study with flexibly dosed

risperidone, all groups showed additional improvement in efficacy scores ([Kent et al. 2013a](#)).

The comparative efficacy of risperidone and haloperidol was assessed in an 8-week double-blind trial that included 30 children and adolescents with DSM-IV autistic disorder ([Miral et al. 2008](#)). Risperidone produced significantly greater reductions in scores on the ABC as well as on other scales used to assess symptoms of autism. An open-label continuation study ([Gencer et al. 2008](#)) of this controlled trial showed that risperidone-treated patients had greater improvement than haloperidol-treated patients on CGI ratings and on the ABC.

In a 24-week randomized trial, combined treatment of risperidone and PT was compared with risperidone alone for the treatment of severe behavioral problems in 124 children with autism spectrum disorder ([Scahill et al. 2012](#)). Combined treatment was superior to medication alone in reduction of noncompliant behavior as assessed by the Home Situation Questionnaire (HSQ). In a 1-year follow-up, there was no significant difference between treatment groups on noncompliant behavior ([Arnold et al. 2012](#)).

## **Aripiprazole**

The efficacy of aripiprazole in the treatment of irritability was evaluated in 218 children and adolescents with DSM-IV autistic disorder in an 8-week double-blind, placebo-controlled trial ([Marcus et al. 2009](#)). Aripiprazole dosages were 5, 10, or 15 mg/day. Compared with placebo, all aripiprazole dosages produced significantly greater improvement on mean scores on the ABC Irritability subscale. The most common adverse events were sedation, tremor, and somnolence. The efficacy of aripiprazole was assessed in another 8-week double-blind, placebo-

controlled trial that included 98 children and adolescents with DSM-IV autistic disorder ([Owen et al. 2009](#)). Aripiprazole dosages were 5, 10, or 15 mg/day. Significantly greater improvements in mean scores on the ABC Irritability subscale were seen with aripiprazole versus placebo. Rates of EPS-related adverse events were 14.9% with aripiprazole and 8% with placebo.

Long-term maintenance treatment with aripiprazole was examined in a double-blind, placebo-controlled relapse-prevention trial for 86 youths with autism spectrum disorder ([Findling et al. 2014](#)). There was no statistically significant difference in time to relapse between aripiprazole and placebo. Relapse rates at week 16 were 35% for the aripiprazole group and 52% for the placebo group.

The efficacy of aripiprazole and risperidone were compared in a 2-month randomized, double-blind trial that included 59 children and adolescents with autism spectrum disorder ([Ghanizadeh et al. 2014](#)). Both aripiprazole and risperidone groups had lower scores on the ABC; there was no statistically significant difference between these medications.

## **Olanzapine**

The efficacy of olanzapine was evaluated in an 8-week double-blind, placebo-controlled trial that included 11 children and adolescents with pervasive developmental disorders ([Hollander et al. 2006](#)). Rates of response (CGI-I score  $\leq 2$ ) were 50% for olanzapine-treated patients and 20% for placebo-treated patients. Olanzapine-treated patients experienced significantly greater weight gain (mean 7.5 lbs for olanzapine vs. 1.5 lbs for placebo-treated patients).

In a 12-week open-label study of olanzapine (mean dosage=7.8 mg/day) in eight patients (ages 5-42 years) with DSM-IV autistic disorder or pervasive developmental disorder not otherwise specified, the six patients who completed the trial showed much or very much global improvement ([Potenza et al. 1999](#)). Significant improvements were found in hyperactivity, social relatedness, affectual responses, sensory responses, language usage, self-injurious behavior, aggression, irritability, anxiety, and depression. The most significant adverse effects were increased appetite and weight gain in six patients and sedation in three patients.

In a 3-month open study of olanzapine (dosage range=1.25-20 mg/day) in 25 subjects (ages 6-16 years) with pervasive developmental disorder, significant global improvement was reported. The most common side effect was weight gain (mean=4.8 kg) ([Kemner et al. 2002](#)).

Olanzapine was compared with haloperidol in a 6-week open trial in 12 children (ages 4-11 years) with DSM-IV autistic disorder ([Malone et al. 2001](#)). Both the olanzapine treatment (mean dosage=7.9 mg/day) and the haloperidol treatment (mean dosage=1.4 mg/day) reduced symptoms of social withdrawal and stereotypies and improved speech and object relations.

## Quetiapine

The effectiveness of quetiapine (dosage range=100-350 mg/day) was assessed in a 16-week open-label trial in six children with DSM-IV autistic disorder ([Martin et al. 1999](#)). No significant behavioral improvements were found from baseline to endpoint.

In a 12-week open-label study of quetiapine in nine adolescents (mean age=14.6 years) with DSM-IV autistic

disorder, only two patients were much or very much improved at study endpoint ([Findling et al. 2004](#)).

## **Ziprasidone**

The efficacy of ziprasidone was evaluated in a 6-week open-label study in 12 adolescents with autism ([Malone et al. 2007](#)). Ziprasidone dosages ranged from 20 mg/day to 160 mg/day (mean dosage=98.3 mg/day). Of the 12 patients, 9 (75%) were considered treatment responders (based on CGI-I scores  $\leq 2$ ). The mean change in QTc from baseline to endpoint was 14.7, which was a statistically significant increase. There was no significant weight change.

The efficacy and safety of ziprasidone in children, adolescents, and young adults with autism were evaluated in an open-label study in which 12 patients (ages 8–20 years) were treated with ziprasidone (mean daily dosage=59.23 mg) for at least 6 weeks ([McDougale et al. 2002](#)). Fifty percent of patients were responders based on a CGI rating of much improved or very much improved. Transient sedation was the most common side effect.

# **Typical Antipsychotics**

## **Haloperidol**

Haloperidol has been the most widely studied typical antipsychotic for the treatment of autism in children and adolescents. In double-blind, placebo-controlled studies, haloperidol has been shown to be significantly superior to placebo in reducing maladaptive behaviors and facilitating learning on discrimination tasks ([Campbell et al. 1982](#)); in increasing retention of discrimination learning and

decreasing maladaptive behaviors in the classroom ([Anderson et al. 1984](#)); in decreasing occurrence of stereotypies and increasing orienting reactions of children ([Cohen et al. 1980](#)); and in decreasing hyperactivity, temper tantrums, withdrawal, and stereotypies and increasing relatedness ([Anderson et al. 1989](#)). Optimal dosages of haloperidol in these studies ranged from 0.25 to 4 mg/day. The most common side effects were sedation, increased irritability, and acute dystonic reactions. Weight gain was modest (0.2 kg) in autistic children who received haloperidol 0.25–3.5 mg/day for a 6-month period ([Silva et al. 1993](#)).

The long-term efficacy of haloperidol was assessed in 48 children (ages 2–8 years) with autism who received haloperidol for 6 months ([Perry et al. 1989](#)). Haloperidol remained effective throughout the 6-month treatment period, and it was equally effective whether it was given continuously or on a discontinuous schedule consisting of 5 days on haloperidol and 2 days on placebo. Children who had symptoms of irritability, angry and labile affect, and uncooperativeness were the best responders to haloperidol.

## Serotonin Reuptake Inhibitors

### Fluoxetine

The efficacy of liquid fluoxetine in treating repetitive behaviors in autism was assessed in 45 children and adolescents with autism spectrum disorder. Subjects were randomly assigned to two 8-week acute phases in a double-blind crossover study ([Hollander et al. 2005](#)). Low-dosage liquid fluoxetine (mean dosage=9.9 mg/day) was superior to placebo in reducing repetitive behaviors.

In an open study of fluoxetine (dosage range=20 mg every other day to 80 mg/day) in 23 patients (ages 7-28 years) with autistic disorder, 15 patients (65%) experienced significant clinical global improvement ([Cook et al. 1992](#)). The most common side effects were restlessness, hyperactivity, agitation, decreased appetite, and insomnia.

## **Fluvoxamine**

A double-blind, placebo-controlled study of fluvoxamine treatment (mean dosage=106.9 mg/day) in 34 children and adolescents with DSM-IV autistic disorder did not find significant clinical improvement with fluvoxamine ([McDougle et al. 2000](#)).

## **Sertraline**

Open-label sertraline (dosage range=25-50 mg/day) was administered to nine children with DSM-IV autistic disorder ([Steingard et al. 1997](#)). Eight of the nine patients showed clinically significant improvement in ability to tolerate changes in their routine or environment without displaying symptoms of anxiety, irritability, or agitation.

## **Citalopram**

The efficacy of citalopram was evaluated for treatment of repetitive behavior in children with autism spectrum disorder ([King et al. 2009](#)). One hundred forty-nine children and adolescents with autism spectrum disorder were randomly assigned to receive citalopram or placebo in a 12-week controlled trial. The mean dosage of citalopram at endpoint was 16.5 mg/day. There was no significant difference in rates of response (CGI-I score  $\leq 2$ ) between citalopram-treated patients (39.2%) and placebo-treated

patients (34.2%). No difference was found in reduction in CY-BOCS scores between the citalopram group and the placebo group. Adverse events that were significantly more common in the citalopram group were increased energy level, impulsiveness, hyperactivity, stereotypy, decreased concentration, diarrhea, insomnia, and dry skin or pruritus.

## **Escitalopram**

In a 10-week open-label study, 28 children and adolescents (ages 6–17 years) with pervasive developmental disorder received escitalopram. There was significant improvement in irritability and clinical global functioning. Twenty-five percent of youths responded at escitalopram daily dosages less than 10 mg, and 36% of youths responded at dosages greater than or equal to 10 mg ([Owley et al. 2005](#)).

# **Other Antidepressants**

## **Clomipramine**

Controlled trials with clomipramine in the treatment of autism spectrum disorder have yielded mixed results. Clomipramine and haloperidol were compared in a placebo-controlled crossover study for 7 weeks with active treatment ([Remington et al. 2001](#)). Thirty-six patients (ages 10–36 years) with DSM-IV autistic disorder were randomly assigned to clomipramine (mean dosage=128.4 mg/day; range=100–150 mg/day), haloperidol (mean dosage=1.3 mg/day; range=1–1.5 mg/day), or placebo. A significant advantage for haloperidol was found on global measures of autism symptom severity and on specific measures of irritability and hyperactivity. Clomipramine was comparable

to haloperidol only among patients who were able to complete a full therapeutic trial. However, significantly fewer patients receiving clomipramine versus haloperidol were able to complete the trial (37.5% vs. 69.7%, respectively) for reasons related to inefficacy, side effects, or behavioral problems.

## **Mirtazapine**

In an open-label study of mirtazapine (dosage range=7.5–45 mg/day; mean=30.3 mg/day) in 26 patients (ages 3–23 years) with pervasive developmental disorders, 9 patients (34.6%) were judged much or very much improved in symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia ([Posey et al. 2001](#)). Mirtazapine did not improve symptoms of social or communication impairment. Common side effects included increased appetite, irritability, and transient sedation.

## **Venlafaxine**

The effectiveness of venlafaxine was assessed in an open retrospective study of 10 patients (ages 3–21 years) with pervasive developmental disorders ([Hollander et al. 2000](#)). Six of 10 patients who received venlafaxine (mean dosage=24.4 mg/day; range=6.25–50 mg/day) over an average of 5 months were much or very much improved. Improvements were observed in repetitive behaviors, restricted interests, social deficits, communication and language function, inattention, and hyperactivity. Side effects of venlafaxine included behavioral activation, nausea, inattention, and polyuria.

## **Reboxetine**

Eleven adolescents with autism spectrum disorder with depressive and ADHD symptoms were treated with reboxetine (maximum dosage 4 mg/day) in a 12-week open-label trial ([Golubchik et al. 2013](#)). Significant, but modest, decreases in depressive and ADHD symptoms were found with reboxetine treatment. Irritability and insomnia were adverse events.

## Anticonvulsants

### Lamotrigine

Twenty-eight children (ages 3–11 years) with DSM-IV autistic disorder participated in a double-blind, placebo-controlled study of lamotrigine (mean main-maintenance dosage=5 mg/kg/day) for a 12-week study period ([Belsito et al. 2001](#)). There were no significant differences between the lamotrigine and placebo groups on severity of behavioral symptoms. Insomnia and hyperactivity were the most frequently reported side effects. No children in the study were withdrawn because of rash.

### Valproate

Three double-blind, placebo-controlled trials have been conducted to assess the efficacy of valproate in the treatment of autism spectrum disorder. In one 8-week trial with 13 children, divalproex was superior to placebo in improvement in repetitive behaviors ([Hollander et al. 2006](#)). In another 8-week trial that included 27 youths with autism spectrum disorder, divalproex significantly reduced symptoms of irritability compared with placebo ([Hollander et al. 2010](#)). However, valproate was not superior to

placebo in reduction of aggression and irritability for 30 youths with pervasive developmental disorders who participated in an 8-week trial ([Hellings et al. 2005](#)).

## **Oxcarbazepine**

In a retrospective case series of 30 youths (ages 5–21 years) with autism spectrum disorder, 14 patients (47%) who were treated with oxcarbazepine (mean final dosage=1,360 mg/day) had CGI-I scores of 2 or lower on ratings of irritability/agitation symptoms ([Douglas et al. 2013](#)).

## **Levetiracetam**

A 10-week double-blind, placebo-controlled trial was conducted to assess the efficacy of levetiracetam in the treatment of 20 children with autism ([Wasserman et al. 2006](#)). The mean maximum dosage of levetiracetam was 862.50 mg/day. There were no significant differences between levetiracetam and placebo on measures of global improvement of autism, aggression and affective instability, and impulsivity and hyperactivity.

# **Other Agents**

## **Lithium**

In a retrospective chart review of 30 children with autism spectrum disorder who were treated with lithium (mean blood level 0.70 mEq/L), 13 youths (43%) were rated as improved on the CGI-I ([Siegel et al. 2014](#)). Vomiting, tremor, fatigue, irritability, and enuresis were the most common adverse effects.

## Clonidine

A double-blind, placebo-controlled crossover study of transdermal clonidine (0.005 mg/kg/day or placebo by a weekly transdermal patch) in nine patients (ages 5–33 years) with autistic disorder was conducted for a total active period of 8 weeks ([Fankhauser et al. 1992](#)). Significant improvement with clonidine, compared with placebo, was found on measures of social relationship, affectual responses, and sensory responses. In a double-blind, placebo-controlled crossover trial of clonidine in eight children with autistic disorder, clonidine was found to be modestly effective in reducing irritability and hyperactivity ([Jaselskis et al. 1992](#)).

## Guanfacine Extended Release

The efficacy of GXR was assessed in an 8-week randomized, placebo-controlled trial that included 62 children with autism spectrum disorder ([Scahill et al. 2015](#)). The GXR modal dose at week 8 was 3 mg/day. The GXR group showed significantly greater decline (43.6%) in scores on the ABC Hyperactivity subscale compared with the placebo group (13.2%). The most common adverse events were drowsiness, fatigue, and decreased appetite.

## Methylphenidate

A meta-analysis of four methylphenidate trials for treatment of ADHD symptoms in children with pervasive developmental disorders showed an effect size of 0.67 ([Reichow et al. 2013](#)). The most likely adverse events were decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal. Use of an extended-release methylphenidate formulation has also been shown to

reduce hyperactive and impulsive behavior in children with autism spectrum disorder and ADHD symptoms ([Pearson et al. 2013](#)).

## **Atomoxetine**

Atomoxetine as a treatment for symptoms of ADHD in children and adolescents with autism spectrum disorder was examined in a double-blind, placebo-controlled 8-week trial that included 97 youths ([Harfterkamp et al. 2012](#)). The atomoxetine dosage was 1.2 mg/kg/day. There was a statistically significant difference between atomoxetine and placebo on change from baseline to endpoint ADHD-RS-IV scores. Adverse effects of nausea, decrease in appetite, fatigue, and early morning awakening were more common in the atomoxetine group than in the placebo group. In a subsequent analysis, atomoxetine did not improve social functioning, but there was some improvement on stereotyped behaviors, inappropriate speech, and fear of change ([Harfterkamp et al. 2014](#)).

In a placebo-controlled crossover trial that included 16 youths with autism spectrum disorder and ADHD symptoms, atomoxetine was superior to placebo in reduction of hyperactivity and impulsivity symptoms as measured on the ABC ([Arnold et al. 2006](#)).

Long-term efficacy and tolerability of atomoxetine were assessed in a 20-week follow-up of an 8-week controlled trial for 88 youths with autism spectrum disorder and autism ([Harfterkamp et al. 2013](#)). Continued treatment with atomoxetine resulted in further improvement of ADHD symptoms. Adverse events, particularly nausea and fatigue, diminished over time with continued treatment.

## **N-Acetylcysteine**

The efficacy of NAC in the treatment of behavioral disturbance was assessed in 33 children with autism in a 12-week double-blind, placebo-controlled trial ([Hardan et al. 2012](#)). The NAC dosage was titrated up to 900 mg three times daily. Compared with placebo, NAC resulted in significant improvement on scores on the ABC Irritability subscale. The most common adverse effects were constipation, nausea and vomiting, and diarrhea. One participant treated with NAC had worsening agitation and irritability and was removed from the study.

## **Bumetanide**

The efficacy of bumetanide for the treatment of 60 children with autism spectrum disorder was evaluated in a 3-month double-blind, placebo-controlled trial ([Lemonnier et al. 2012](#)). The bumetanide dosage was 1 mg/day. Bumetanide was significantly superior to placebo in reduction of symptoms on the primary outcome measure, the Childhood Autism Rating Scale (CARS). Occasional mild hypokalemia was an adverse event.

## **Intranasal Oxytocin**

Intranasal oxytocin has been examined as a treatment for autism spectrum disorder in controlled trials and a long-term open-label study. Oxytocin nasal spray (18 or 24 international units [IU]) or placebo was administered to 16 youths with autism spectrum disorder in a double-blind, placebo-controlled crossover design ([Guastella et al. 2010](#)). Compared with placebo, oxytocin significantly improved emotion recognition.

In a double-blind, placebo-controlled trial, 36 male youths with autism spectrum disorder received 24 or 12 IU of

oxytocin or placebo over a 4-day period ([Dadds et al. 2014](#)). There were no significant differences between intranasal oxytocin and placebo on measures of social interaction skills, repetitive behaviors, and emotion recognition.

In a 7-month open-label study, intranasal oxytocin was administered (8- to 24-IU dose every 2 months) to eight male youths with autism spectrum disorder ([Tachibana et al. 2013](#)). Six of eight youths showed improvement in communication and social interaction on the Autism Diagnostic Observation Schedule—Generic (ADOS-G).

## **Arbaclofen**

The efficacy of arbaclofen was assessed in a 12-week double-blind, placebo-controlled trial that included 150 children, adolescents, and young adults ([Delahunty et al. 2013](#)). Arbaclofen was titrated to a maximum of 10 mg three times daily for youths ages 5–11 years and 15 mg three times daily for youths ages 12–21 years. There was no significant difference between arbaclofen and placebo in improving lethargy or social withdrawal.

# **Adjunctive Treatments**

## **Memantine**

Memantine as adjunctive treatment to risperidone for autism spectrum disorder was assessed in a 10-week double-blind, placebo-controlled trial for 40 children ([Ghaleiha et al. 2013a](#)). The dosage of memantine was titrated to 20 mg/day, and the risperidone dosage was titrated to 3 mg/day. Compared with the placebo group, the group that received adjunctive memantine had a

significantly greater reduction in the Irritability score on the ABC—Community version. There was no significant difference in adverse effects between the groups.

## **Amantadine**

Amantadine as adjunctive treatment to risperidone for treatment of 40 children with autism spectrum disorder was evaluated in a 10-week double-blind, placebo-controlled trial ([Mohammadi et al. 2013](#)). Amantadine was titrated to 100–150 mg/day, and risperidone was titrated to 1–2 mg/day. Compared with the placebo group, the adjunctive amantadine group had a significantly greater reduction in Hyperactivity and Irritability scores on the ABC—Community version. There were no significant adverse effects among the groups.

## **Riluzole**

The efficacy of riluzole as adjunctive treatment to risperidone was assessed in a 10-week double-blind, placebo-controlled trial for 40 children with autism spectrum disorder ([Ghaleiha et al. 2013b](#)). Riluzole was titrated to 50–100 mg/day, and risperidone was titrated to 2–3 mg/day. Significantly greater improvement in irritability, as assessed by the ABC—Community version, was found for the adjunctive riluzole group than the placebo group. Increased appetite and weight gain were more common in the riluzole group than the placebo group.

## **Buspirone**

Buspirone as adjunctive treatment to risperidone was evaluated in an 8-week double-blind, placebo-controlled trial for 40 youths with autism ([Ghanizadeh and](#)

[Ayoozbadehshirazi 2015](#)). The mean dosage of buspirone was 6.7 mg/day. Compared with the placebo group, the adjunctive buspirone group showed a significantly greater reduction in the Irritability subscale score of the ABC—Community version. The most common adverse events in the buspirone group were increased appetite, drowsiness, and fatigue.

## **Celecoxib**

Adjunctive treatment with celecoxib to risperidone was evaluated in a 10-week double-blind, placebo-controlled trial that included 40 children with autism ([Asadabadi et al. 2013](#)). Celecoxib was titrated to 300 mg/day and risperidone to 3 mg/day. Adjunctive celecoxib was superior to placebo in reducing irritability, social withdrawal, and stereotypy as measured on the ABC—Community version.

## **Pentoxifylline**

The efficacy of adjunctive pentoxifylline to risperidone was assessed in a 10-week double-blind, placebo-controlled trial that included 40 children with a DSM-IV-TR ([American Psychiatric Association 2000](#)) diagnosis of autistic disorder ([Akhondzadeh et al. 2010](#)). Pentoxifylline was titrated to 600 mg/day, and risperidone was titrated to 3 mg/day. Adjunctive pentoxifylline was superior to placebo in reducing scores on the ABC—Community version subscales for irritability, lethargy/social withdrawal, stereotypic behavior, hyperactivity/noncompliance, and inappropriate speech. There was no significant difference between the groups in adverse events.

## **N-Acetylcysteine**

NAC as adjunctive treatment to risperidone for treatment of irritability in autism spectrum disorder has been evaluated in two double-blind, placebo-controlled studies. In a 10-week study that included 40 children with autism spectrum disorder, the NAC dosage was 600–900 mg/day ([Nikoo et al. 2015](#)). In an 8-week study that included 40 children with autism spectrum disorder, the NAC dosage was 1,200 mg/day ([Ghanizadeh and Moghimi-Sarani 2013](#)). Adjunctive NAC was superior to placebo in the reduction of irritability as assessed by the ABC in both studies.

## Clinical Recommendations for Autism Spectrum Disorder

Although there is no evidence that pharmacotherapy is effective in treating the core social and communication deficits in autism spectrum disorder, medications have been shown to be useful in treating associated symptoms, such as hyperactivity, inattention, stereotypies, self-injurious behavior, tantrums, aggression, mood lability, and anxiety. Antipsychotics may decrease withdrawal, stereotypies, and aggression and may facilitate learning. To date, most available data support the use of risperidone or aripiprazole for treating irritability, aggression, self-injurious behavior, temper tantrums, and mood lability associated with autism spectrum disorder in children and adolescents. Serotonin reuptake inhibitors and other antidepressants have been shown to reduce compulsions, anxiety, and depression in children with autism spectrum disorder. Other agents that may be beneficial to treat associated symptoms are  $\alpha_2$  agonists, stimulants, mood

stabilizers, and norepinephrine reuptake inhibitors ([Volkmar et al. 2014](#)).

Limited data are available on the long-term use of pharmacotherapy in children with autism spectrum disorder. After receiving an intermediate-length (4- to 6-month) course of treatment with risperidone, children withdrawn from the medication through placebo substitution had high relapse rates ([Research Units on Pediatric Psychopharmacology Autism Network 2005](#); [Troost et al. 2005](#)). Therefore, clinicians must weigh the risk-benefit ratio of maintenance medication treatment in this population and carefully monitor children for side effects.

## Appendix

# Psychotropic Medications Commonly Prescribed for Children and Adolescents

This appendix describes common classes of psychotropic medications used to treat children and adolescents. Dosing information, monitoring schedules, and common side effects are presented for each medication class.

## Antidepressants

### Dosage and Monitoring

The starting dosages and target dosages of antidepressants for children and adolescents are listed in [Table 55-1](#).

**TABLE 55-1. Clinical use of antidepressants in children and adolescents**

Medication	Typical starting dose (mg)		Target dosage (mg/day)
	Child	Adolescent	

*Note.* bid=twice daily.

Medication	Typical starting dose (mg)		Target dosage (mg/day)
	Child	Adolescent	
Selective serotonin reuptake inhibitors			
Citalopram	5-10	10	20-40
Escitalopram	5	10	10-20
Fluoxetine	5-10	10	20-40
Paroxetine	5-10	10	20-40
Sertraline	25	50	100-200
Mirtazapine	15	15	30-45
Venlafaxine	37.5	37.5	150-225
Bupropion	50 bid	50 bid	100-200
Duloxetine	30	30	60-120

*Note.* bid=twice daily.

Premedication laboratory testing should include complete blood count, blood chemistries, and liver function tests. Blood pressure should be monitored during dosage titration with venlafaxine.

The [U.S. Food and Drug Administration \(2007\)](#) issued the following black box warning, which applies to all antidepressants:

Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorders. Anyone considering the use of [Name of Antidepressant] or any other antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antidepressants compared with placebo in adults beyond age 24 years; there was a reduction in risk with antidepressants compared with placebo in adults ages 65 years and older. Depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide. Patients of all ages who are started on antidepressant therapy should be monitored

appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber.

## Side Effects

Common side effects of selective serotonin reuptake inhibitors (SSRIs) are headache, nausea, abdominal pain, dry mouth, insomnia, and somnolence ([Emslie et al. 2002](#); [Keller et al. 2001](#); [Wagner et al. 2003a, 2004b, 2006a](#)). Potential serious adverse events include serotonin syndrome, extrapyramidal side effects (EPS) (tics, myoclonus), amotivational syndrome, and increased bleeding ([Hammerness et al. 2006](#)). A major advantage of SSRIs is their safety in overdose ([Barbey and Roose 1998](#)).

Common side effects of mirtazapine are somnolence, increased appetite, weight gain, dizziness, dry mouth, and constipation ([Green 2001](#)).

Common side effects of venlafaxine include anorexia, abdominal pain, insomnia, somnolence, dizziness, dry mouth, increased sweating and nervousness, and elevated blood pressure with dosage increase ([Emslie et al. 2007](#); [Green 2001](#)).

Common side effects of bupropion are headache, nausea, rash, irritability, drowsiness, fatigue, and anorexia ([Barrickman et al. 1995](#); [Connors et al. 1996](#); [Daviss et al. 2001](#)). Bupropion is contraindicated in children with seizure disorders, because it may lower the seizure threshold.

Common side effects of duloxetine are nausea, vomiting, nasopharyngitis, abdominal pain, headache, and somnolence ([Atkinson et al. 2014](#); [Emslie et al. 2014](#)).

---

## Atomoxetine

---

## Dosage and Monitoring

Atomoxetine can be taken in the late afternoon or evening, whereas stimulants generally cannot; atomoxetine may have less pronounced effects on appetite and sleep than stimulants, although it may produce relatively more nausea or sedation. Gastrointestinal distress can be minimized by taking the medication after a meal. In children and young adolescents, atomoxetine is initiated at a dosage of 0.3 mg/kg/day and titrated over 1–3 weeks to a maximum dosage of 1.2–1.8 mg/kg/day ([Kratovich et al. 2003](#)). In adults or adult-sized adolescents, atomoxetine should be started at 40 mg/day and titrated to 80–100 mg/day over 1–3 weeks, if needed ([Kratovich et al. 2003](#)). Atomoxetine's labeling recommends both once-daily and twice-daily dosing, although its elimination half-life of 5 hours (as well as clinical experience) suggests that twice-daily dosing (early morning and early evening) is more effective and less prone to cause side effects. [Michelson et al. \(2002\)](#) showed that although atomoxetine was superior to placebo at week 1 of the trial, its greatest effects were observed at week 6, suggesting that patients should be maintained at the full therapeutic dosage for at least several weeks for the drug to reach its full effects.

## Side Effects

Side effects that occurred at higher rates with atomoxetine than with placebo in clinical trials included gastrointestinal distress, sedation, and decreased appetite. These can generally be managed by dosage adjustment and often attenuate with time. In December 2004, the FDA announced a new warning for atomoxetine due to reports of two patients (an adult and a child) who developed severe liver disease ([U.S. Food and Drug Administration 2004c](#)). Both patients recovered. The FDA has also issued an alert regarding suicidal thinking with atomoxetine in children and adolescents ([U.S. Food and Drug Administration 2005](#)). A black box warning is included in the package insert. In 12 controlled trials involving 1,357 patients receiving atomoxetine and 851 receiving placebo, the average risk of suicidal thinking was 4 per 1,000 patients in the atomoxetine-treated group versus none in the placebo group.

---

# Atypical Antipsychotics

---

## Dosage and Monitoring

Usual starting dosages and target dosages of atypical antipsychotics are listed in [Table 55-2](#).

---

**TABLE 55-2. Clinical use of atypical antipsychotics in children and adolescents**

---

Medication	Typical starting dose (mg)	Target dosage (mg/day)
Clozapine	25 bid	200-400
Olanzapine	2.5 bid	10-20
Quetiapine	50 bid	400-600
Risperidone	0.25 bid	1-2
Ziprasidone	20 bid	80-120
Aripiprazole	2.5-5.0 hs	10-25
Asenapine	2.5 sublingually bid	2.5-10 sublingually bid
Paliperidone ER		
Weight <51 kg	3	3-6
Weight ≥51 kg	3	3-12

---

*Note.* bid=twice daily; ER=extended release; hs=at bedtime.

*Source.* [DelBello et al. 2006](#).

Premedication laboratory testing should include complete blood count, blood chemistries, and liver function tests. In addition, the recommendations of the [American Diabetes Association et al. \(2004\)](#) should be followed. These include baseline BMI, waist circumference, blood pressure, and fasting glucose and lipid panels. BMI should be followed monthly for 3 months and then measured quarterly. Blood

pressure, fasting glucose, and lipid panels should be followed up at 3 months and then yearly. Monitoring should also be done for EPS.

## Side Effects

Side effects of atypical antipsychotics include weight gain, dyslipidemia, insulin resistance and diabetes, hyperprolactinemia, EPS and akathisia, QTc prolongation, sedation, liver toxicity, neutropenia, and neuroleptic malignant syndrome. Clozapine has also been associated with seizures, agranulocytosis, and myocarditis ([Correll et al. 2006](#)).

---

## Clonidine

---

### Dosage and Monitoring

Clonidine is initiated at 0.05 mg/day, with dosage increases of 0.05 mg every 3 days. Typical dosages for attention-deficit/hyperactivity disorder (ADHD) are in the range of 0.15–0.3 mg/day (on a three-times-per-day schedule). Transdermal clonidine delivers dosages of 0.1, 0.2, or 0.3 mg/day. During initial treatment, a temporary worsening of motor and phonic tics in Tourette syndrome may occur, which usually resolves within 2–4 weeks. Clonidine should be tapered by 0.05 mg/day during discontinuation ([Hunt et al. 1990](#)).

Due to reports of adverse cardiovascular side effects in children taking clonidine, recommendations have been made regarding cardiovascular monitoring ([Cantwell et al. 1997](#)). Pulse and blood pressure should be measured at baseline, weekly during dosage titration, and every 4–6 weeks during maintenance treatment. Electrocardiograms (ECGs) should be obtained at baseline and after the maximum dosage of clonidine is achieved. Abrupt discontinuation of clonidine is not recommended, because it increases the risk of adverse cardiovascular side effects, particularly hypertension.

## Side Effects

Common side effects of clonidine in children are sedation, depression, irritability, hypotension, sleep disturbance, dry mouth, and dizziness. Skin irritation and erythema are common with the clonidine patch ([Connor et al. 1999](#); [Hunt et al. 1990](#)). Rebound tachycardia and hypertension may occur if clonidine is abruptly discontinued, particularly after chronic use ([Popper 2000](#)).

Safety concerns have been raised about the combination of clonidine and methylphenidate, following the report of four cases of sudden death in children taking this medication combination ([Cantwell et al. 1997](#); [Fenichel 1995](#)). [Swanson et al. \(1995a\)](#) described two types of clonidine-related cardiovascular side effects. In one type, fatigue and sedation were associated with a decrease in pulse and blood pressure as well as changes in ECG. In the other type, tachycardia and tachypnea occurred, which led to anxiety, fever, and changes in mental status. Adverse cardiovascular side effects, including bradycardia and depressed level of consciousness, have been reported with clonidine overdose in children ([Kappagoda et al. 1998](#)). However, in a retrospective study of 42 children treated with clonidine alone or clonidine plus stimulants, no systematic effects were found on ECG parameters of pulse rate or QTc intervals ([Kofoed et al. 1999](#)).

---

## Guanfacine

---

### Dosage and Monitoring

Guanfacine is initiated at a daily dosage of 0.5 mg, with an upward titration of 0.5 mg every 3 days, based on clinical response and tolerability, to a maximum daily dosage of 4 mg ([Hunt et al. 1995](#)).

Pulse and blood pressure should be monitored during guanfacine treatment. Guanfacine should be tapered over a 4-day period upon discontinuation.

## Side Effects

Common side effects of guanfacine in children are sedation, fatigue, headache, dizziness, stomachache, and decreased appetite ([Chappell et al. 1995](#); [Hunt et al. 1995](#); [Melmed et al. 2006](#); [Scahill et al. 2001](#)). Rebound hypertension, nervousness, and anxiety may occur if guanfacine is abruptly discontinued ([Green 2001](#)).

---

## Mood Stabilizers

---

### Dosage and Monitoring

The starting dosages, target dosages, and therapeutic serum levels of mood stabilizers are listed in [Table 55-3](#).

---

**TABLE 55-3. Clinical use of mood stabilizers in children and adolescents**

---

Medication	Typical starting dose (mg)	Target dosage	Therapeutic serum level
Carbamazepine	7 mg/kg/day	Based on response and serum level	8–11 µg/L
Lamotrigine	12.5 mg/day	Based on response	N/A
Lithium	25 mg/kg/day (2–3 daily doses)	30 mg/kg/day (2–3 daily doses)	0.8–1.2 mEq/L

---

*Note.* bid=twice daily; N/A=not applicable.

*Source.* [DelBello and Kowatch 2006](#).

---

<b>Medication</b>	<b>Typical starting dose (mg)</b>	<b>Target dosage</b>	<b>Therapeutic serum level</b>
Oxcarbazepine	150 mg bid	20–29 kg: 900 mg/day 30–39 kg: 1,200 mg/day >39 kg: 1,800 mg/day	N/A
Topiramate	25 mg/day	100–400 mg/day	N/A
Valproic acid, divalproex	20 mg/kg/day (2 daily doses)	20 mg/kg/day (2–3 daily doses)	90–120 µg/mL

*Note.* bid=twice daily; N/A=not applicable.

*Source.* [DelBello and Kowatch 2006](#).

Premedication laboratory testing in general should include complete blood count, liver function tests, and a pregnancy test (for females).

For lithium, baseline thyroid function tests, electrolytes, urinalysis, blood urea nitrogen, creatinine, and serum calcium should also be obtained. Lithium levels, renal function, thyroid function, and urinalysis should be monitored every 3–6 months.

For individuals taking divalproex, drug serum levels, complete blood count, and liver function tests should be monitored every 3–6 months. Because of concerns about a possible relationship between divalproex and polycystic ovarian syndrome (PCOS; [Rasgon 2004](#)), female adolescents taking divalproex should be monitored for signs of PCOS, including menstrual abnormalities, weight gain, acne, and hirsutism ([DelBello and Kowatch 2006](#); [McClellan et al. 2007](#)). Parents and their female adolescents should be apprised about this possible association prior to initiating medication.

For oxcarbazepine, children should be monitored for hyponatremia.

## Side Effects

Common side effects of lithium in children and adolescents include hypothyroidism, nausea, polyuria, polydipsia, acne, tremor, and weight gain ([DelBello and Kowatch 2006](#)).

Common side effects of divalproex in children and adolescents include weight gain, nausea, sedation, and tremor ([DelBello and Kowatch 2006](#)). Concerns have been raised about a possible association between divalproex and PCOS ([Rasgon 2004](#)). Other potential adverse effects of concern are hepatic failure, pancreatitis, thrombocytopenia, behavioral deterioration, and hair loss ([Davanzo and McCracken 2000](#); [Green 2001](#)).

Side effects of topiramate include decreased appetite, weight loss, nausea, diarrhea, paresthesias, somnolence, and word-finding difficulties ([DelBello and Kowatch 2006](#); [DelBello et al. 2005](#)).

Side effects of oxcarbazepine in children include dizziness, nausea, somnolence, diplopia, fatigue, and rash ([Wagner et al. 2006b](#)). Hyponatremia is also a side effect of oxcarbazepine.

Common side effects of lamotrigine in children include ataxia, nausea, vomiting, and constipation. Of particular concern, the incidence of serious rash, including Stevens-Johnson syndrome, in pediatric populations is reported to be 1%. This high incidence of serious rash may be attributable to the prior use of high dosages of lamotrigine with concomitant divalproex ([Messenheimer 1998](#)). The current dosing guidelines may reduce this rash incidence in pediatric patients.

---

## Psychostimulants

---

### Dosage and Monitoring

The American Academy of Child and Adolescent Psychiatry has developed practice parameters for the diagnosis and treatment of ADHD ([Pliszka and AACAP Work Group on Quality Issues 2007](#)). A wide variety of stimulant preparations are available; [Table 55-4](#)

describes their use in clinical practice. Each stimulant has a maximum dosage suggested by the FDA-approved package insert, but higher off-label dosages are commonly used with careful monitoring. For safety monitoring, a patient's pulse, blood pressure, weight, and height should be obtained at baseline and at least annually. No laboratory measures or ECG monitoring is required.

**TABLE 55-4. Clinical use of psychostimulants in children and adolescents**

<b>Medication</b>	<b>Dose strengths</b>	<b>Typical starting dosage</b>	<b>FDA max/day</b>	<b>Off-label max/day</b>
<b>Amphetamine preparations</b>				
Adderall	5, 7.5, 10, 12.5, 15, 20, 30 mg	3–5 yr: 2.5 mg qd  ≥6 yr: 5 mg qd–bid	40 mg	≥50 kg: 60 mg
Dexedrine	5 mg	3–5 yr: 2.5 mg qd  ≥6 yr: 5 mg qd–bid	40 mg	≥50 kg: 60 mg
Dextrostat	5, 10 mg	3–5 yr: 2.5 mg qd	40 mg	≥50 kg: 60 mg

*Note.* bid=twice daily; CD=controlled delivery (extended release); ER=extended release; FDA=U.S. Food and Drug Administration; LA=long acting (extended release); qam=every morning; qd=once daily; SR=sustained release; XR=extended release.

<b>Medication</b>	<b>Dose strengths</b>	<b>Typical starting dosage</b>	<b>FDA max/day</b>	<b>Off-label max/day</b>
		≥6 yr: 5 mg qd-bid		
Dexedrine Spansule	5, 10, 15 mg	≥6 yr: 5-10 mg qd-bid	40 mg	≥50 kg: 60 mg
Adderall XR	5, 10, 15, 20, 25, 30 mg	≥6 yr: 10 mg qd	30 mg	≥50 kg: 60 mg
Vyvanse	30, 50, 70 mg	30 mg qd	70 mg	Not determined
<b>Methylphenidate preparations</b>				
Focalin	2.5, 5, 10 mg	2.5 mg bid	20 mg	50 mg
Focalin XR	5, 10, 15, 20 mg	5 mg qam	30 mg	50 mg
Methylin	5, 10, 20 mg	5 mg bid	60 mg	≥50 kg: 100 mg
Metadate ER	10, 20 mg	10 mg qam	60 mg	≥50 kg: 100 mg

---

## Side Effects

Common side effects of psychostimulants are insomnia, diminished appetite, weight loss, irritability, abdominal pain, and headaches (Pliszka and AACAP Work Group on Quality Issues 2007). Rebound symptoms of worsening behavior may occur when the effects of the short-acting psychostimulants dissipate. Switching to sustained-release or longer-acting psychostimulants may ameliorate rebound symptoms.

Although earlier reports of a protective effect from psychostimulants were not borne out by a later study (Molina et al. 2009), there is no evidence that psychostimulants increase substance abuse in youth with ADHD. Motor tics may develop during treatment with stimulants, but one study reported no increase in tics for children with or without preexisting tics who received typical clinical dosages of methylphenidate compared with placebo (Law and Schachar 1999).

The FDA and its Pediatric Advisory Committee have reviewed data regarding psychiatric adverse events related to stimulant medication (U.S. Food and Drug Administration 2006). Data from controlled trials and postmarketing safety data from sponsors and the FDA Adverse Events Reporting System (AERS), also referred to as MedWatch, were reviewed. For most of the agents, psychiatric adverse events were slightly more common in the groups given active drug rather than placebo in the controlled trials, but these differences did not reach statistical significance (Mosholder 2006). Postmarketing safety data were also reviewed for reports of mania/psychotic symptoms, aggression, and suicidality (Gelperin 2006). Rare events of suicidal thoughts, manic-like activation, or psychosis were reported. At the time, the Pediatric Advisory Committee did not recommend a black box warning regarding psychiatric adverse events but did suggest clarifying labeling regarding these phenomena. No changes to the stimulant medication labeling were suggested regarding suicide or suicidal ideation.

There have been rare reports of sudden death in patients taking stimulant medication. Villalaba (2006) reported that the FDA has records of 20 cases of sudden death with amphetamine or dextroamphetamine (14 children, 6 adults), and of 14 pediatric and 4 adult cases of sudden death with methylphenidate. It is important to note that the rate of sudden death in the general pediatric

population has been estimated at 1.3–8.5 per 100,000 patient-years ([Liberthson 1996](#)). The rate of sudden death among individuals with a history of congenital heart disease can be as high as 6% by age 20 years ([Liberthson 1996](#)). [Villalaba \(2006\)](#) estimated the rate of sudden death in children treated for ADHD during the period encompassing January 1, 1992, to December 31, 2004, to be 0.2 per 100,000 patient-years for methylphenidate, 0.3 per 100,000 patient-years for amphetamine, and 0.5 per 100,000 patient-years for atomoxetine (the differences between the agents are not clinically meaningful). Because the rate of sudden death in children taking ADHD medications does not appear to exceed the base rate of sudden death in the general population, cardiac monitoring of healthy children during treatment with stimulants is not required. Children with preexisting heart disease (or significant symptoms suggesting the condition) should obtain a cardiology consultation prior to taking a stimulant.

[Poulton \(2005\)](#) reviewed growth data and concluded that stimulant treatment may be associated with a reduction in expected height gain, at least in the first 1–3 years of treatment. The National Institute of Mental Health (NIMH) Multimodal Treatment of ADHD (MTA) study showed reduced growth rates in patients with ADHD after 2 years of stimulant treatment compared with patients who received no medication ([MTA Cooperative Group 2004](#)), and these deficits persisted at 36 months ([Swanson et al. 2007](#)). The Preschool ADHD Treatment Study (PATs) followed a group of 140 preschoolers who received methylphenidate for ADHD for up to a year ([Swanson et al. 2006](#)). The subjects had less than expected mean gains in height (–1.38 cm) and weight (–1.3 kg). [Charach et al. \(2006\)](#) found that higher dosages of stimulants correlated with reduced gains in height and weight and that the effect did not become significant until the dosage in methylphenidate equivalents was >2.5 mg/kg/day for 4 years. [Pliszka et al. \(2006b\)](#) did not find that children with ADHD treated with monotherapy with either amphetamine or methylphenidate showed any failure to achieve expected height; furthermore, the two stimulant classes did not have a differential effect on height, although amphetamine had a somewhat greater effect on weight than did methylphenidate. The subjects in this study had drug holidays averaging 31% of the time during their treatment

course, which may have contributed to the lack of effect of the stimulant on height.

In assessing for clinically significant growth reduction, it is recommended to use serial plotting of height and weight on growth charts labeled with lines showing the major percentiles (5th, 10th, 25th, 50th, 75th, 90th, and 95th) ([Mei et al. 2004](#)). This should occur one to two times per year and more frequently if practical. A change in height or weight that crosses two percentile lines suggests an aberrant growth trajectory. In these cases, a drug holiday should be considered if return of symptoms during weekends or summers does not lead to marked impairment of functioning. The clinician should also consider switching the patient to another ADHD medication. It is important for the clinician to carefully balance the benefits of medication treatment with the risks of small reductions in height gain, which as of yet have not been shown to be related to reductions in adult height ([Klein and Mannuzza 1988](#); [Kramer et al. 2000](#); [Weiss and Hechtman 2003](#)).

## CHAPTER 56

# Treatment During Late Life

Steven P. Roose, M.D.

Bruce G. Pollock, M.D., Ph.D.

D. P. Devanand, M.D.

Adverse events caused by medication are a significant cause of morbidity and mortality in the elderly. In a large study of ambulatory Medicare enrollees, 38% of adverse drug events were serious, life-threatening, or fatal and 28% were considered preventable ([Gurwitz et al. 2003](#)). Moreover, psychotropics are among the most common medications associated with preventable adverse drug events in elderly patients in long-term care settings ([Gurwitz et al. 2000](#)).

---

# Pharmacokinetics of Psychotropic Medications in the Elderly

---

In general, age-associated pharmacokinetic changes result in higher and more variable drug concentrations. Nonetheless, specific information on the pharmacokinetics of most psychoactive medications is inadequate, particularly with regard to medical comorbidities and potential drug interactions. The limited information that does exist for older subjects is largely derived from classical pharmacokinetic modeling. Traditional pharmacokinetic studies require a large number of plasma drug samples obtained from a small number (i.e., 6–12) of volunteers. These single-dosage pharmacokinetic studies usually are not adequate to rule out the possibility of nonlinear kinetics. Moreover, age or illness-associated differences in pharmacodynamics are not interpretable in the absence of drug concentration data. Population pharmacokinetics provides a means for addressing heterogeneous drug exposure for elders using minimal sampling methods ([Bigos et al. 2006](#)). For example, using this approach, we have examined age and cytochrome P450 (CYP) genotype effects for citalopram, escitalopram, and paroxetine ([Bies et al. 2004](#); [Feng et al. 2006](#); [Jin et al. 2010](#)).

Although individuals older than 65 years account for more than one-third of prescription drug expenditures in the United States, they are often excluded from clinical and regulatory trials. In addition, the trials that do include elders rarely include the “oldest old” (i.e., 85+ years), those having multiple comorbidities, or those taking multiple

medications. These exclusions raise questions about the generalizability of psychotropic data to the frail elderly.

Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug (Table 56-1). The multidimensional changes associated with aging are heterogeneous, and only generalizations can be made (Lotrich and Pollock 2005).

**TABLE 56-1. Physiological changes in the elderly associated with altered pharmacokinetics**

Organ system	Change	Pharmacokinetic consequence
Gastrointestinal tract	Decreased intestinal and splanchnic blood flow	Decreased rate of drug absorption
Circulatory	Decreased concentration of plasma albumin and increased $\alpha_1$ -acid glycoprotein	Increased or decreased free concentration of drugs in plasma
Kidney	Decreased glomerular filtration rate	Decreased renal clearance of active metabolites

<b>Organ system</b>	<b>Change</b>	<b>Pharmacokinetic consequence</b>
Muscle	Decreased lean body mass and increased adipose tissue	Altered volume of distribution of lipid-soluble drugs, leading to increased elimination half-life
Liver	Decreased liver size; decreased hepatic blood flow; minimal effects on cytochrome P450 enzyme activity	Decreased hepatic clearance

## Absorption

Although absorption of nutrients is often impaired in the elderly, the rate and extent of passive drug absorption are not affected by normal aging. Antacids, high-fiber supplements, and cholestyramine may significantly diminish the absorption of medications.

## Distribution

For most psychotropics that are lipid soluble, the loss of lean body mass with aging will lead to increases in their volumes of distribution, resulting in longer half-lives and

drug accumulation. This is because a drug's half-life is directly proportional to its apparent volume of distribution. Conversely, for water-soluble drugs such as lithium and digoxin, volumes of distribution will be diminished in older patients, reducing the margin of safety after acute increases in plasma drug concentration.

Reductions in serum albumin with age and possible increases in  $\alpha_1$ -acid glycoprotein with illness may affect the extent of drug bound to plasma proteins. However, it is now recognized that changes in plasma protein binding are of clinical significance only when therapeutic drug monitoring is used to adjust dosing, because total drug concentrations (free+protein bound) are usually reported ([Benet and Hoener 2002](#)). Total drug levels may be interpreted as too low if a drug's free fraction is increased by diminished plasma proteins or drug displacement. The use of free drug levels in older patients has been found to be useful for lidocaine, theophylline, phenytoin, and digitoxin.

## Metabolism

Available evidence suggests that there is no uniform age-associated decline in liver metabolism by CYP enzymes ([Pollock et al. 1992b](#); [Schmucker 2001](#)). Nonetheless, reductions in hepatic mass and blood flow with aging place greater emphasis on interindividual differences in drug metabolic capacity. These metabolic differences may be either genetic or the result of interactions from multiple medications. Enzyme specificity suggests that inhibition or induction of a given CYP enzyme will affect all drugs metabolized by that specific enzyme. Updated information on CYP-mediated drug-drug interactions is available at the

University of Indiana School of Medicine's "Drug Interactions" Web page (see [Flockhart 2007](#)).

CYP2D6 is the enzyme responsible for metabolizing tricyclic antidepressants (TCAs) and venlafaxine as well as several older antipsychotics and risperidone. Among the white population, 5%-10% are genetically poor CYP2D6 metabolizers.

Drugs metabolized by CYP3A4, such as alprazolam, triazolam, sertraline, and mirtazapine, appear to be cleared less well in elderly patients ([Greenblatt et al. 1991](#); [Ronfeld et al. 1997](#); [Timmer et al. 1996](#)). However, this may be because metabolism of CYP3A4 drugs is typically perfusion limited (i.e., dependent on hepatic blood flow, which is known to decline substantially with age) ([Wynne et al. 1990](#)). CYP3A4 makes up 30% of total hepatic CYP and nearly all of drug-metabolizing enzyme in the small bowel, and therefore is substantially responsible for "first-pass" or presystemic drug disposition ([Shimada et al. 1994](#)). Serious toxicity has occurred when the 3A4-mediated clearance of terfenadine, astemizole, cisapride, cerivastatin, midazolam, and triazolam was inhibited ([Dresser et al. 2000](#)). CYP3A4 activity may be inhibited by grapefruit juice, protease inhibitors, macrolide antibiotics, and triazole antifungals. Among antidepressants, fluvoxamine is the most potent inhibitor of CYP3A4, followed by fluoxetine, through its demethylated metabolite. The very long half-life of norfluoxetine may result in interactions occurring many weeks after the initiation of fluoxetine treatment. The 3A4 enzyme is also potently induced by other drugs, such as carbamazepine, phenytoin, topiramate, modafinil, barbiturates, steroids, and St. John's wort. CYP3A4 induction will increase the likelihood of therapeutic failure for concurrently prescribed 3A4 substrate drugs. Many

CYP3A4 inhibitors (e.g., diltiazem) and inducers (e.g., St. John's wort) also have been found to inhibit or induce the *P*-glycoprotein drug transporter, amplifying their effects on 3A4 ([Yu 1999](#)).

CYP1A2 metabolizes clozapine, olanzapine, fluvoxamine, and theophylline and contributes to the demethylation of some tertiary TCAs. This enzyme is induced by cigarette smoking, cruciferous vegetables, and charcoaled meats. CYP 2C9 metabolizes several drugs with a narrow therapeutic index (i.e., phenytoin, tolbutamide, ibuprofen, and warfarin). It is therefore important to recognize that this enzyme may be inhibited by fluvoxamine and fluoxetine.

## Excretion

Age-associated decline in renal clearance may affect excretion of psychotropic drug metabolites and lithium in older patients. The magnitude of this decline varies greatly among the aged ([Pollock et al. 1992b](#)), being exacerbated by concomitant conditions (e.g., diabetes and hypertension) and medications (e.g., nonsteroidal anti-inflammatory drugs). Accumulation of active TCA metabolites in the elderly was previously a subject of concern ([Pollock et al. 1992a](#)). Higher concentrations of bupropion and venlafaxine metabolites also have been observed in older patients and those with renal impairment, with uncertain clinical consequences.

---

## Pharmacodynamics of Psychotropic Medications in the

# Elderly

---

Interindividual differences in pharmacodynamics become evident when those with similar plasma drug concentrations experience different effects. In general, older patients are more sensitive to adverse effects of psychotropics at lower concentrations. Homeostatic mechanisms, such as postural control, water balance, orthostatic circulatory responses, and thermoregulation, are frequently less robust in the aged. This factor may interfere with the ability to physiologically adapt to medication. For example, all psychotropics, including selective serotonin reuptake inhibitors (SSRIs), may increase the risk of falls and hip fractures ([Liu et al. 1998](#)). Similarly, the syndrome of inappropriate antidiuretic hormone secretion has been reported as an age-associated adverse effect of all SSRIs and of venlafaxine ([Kirby and Ames 2001](#)).

Reductions in dopamine or acetylcholine function with age may increase sensitivity to antipsychotics and SSRIs (which indirectly reduce dopamine outflow) as well as medications with antimuscarinic effects ([Gerretsen and Pollock 2011](#); [Graff-Guerrero et al. 2015](#)). Even low serum anticholinergic levels may be associated with cognitive impairment in depressed and nondepressed elderly persons ([Mulsant et al. 2003](#); [Nebes et al. 2012](#)). Unfortunately, anticholinergic drugs continue to be widely prescribed in older patients ([Chew et al. 2008](#); [Roe et al. 2002](#)).

Anticoagulant-antidepressant interactions may be both pharmacokinetic and pharmacodynamic. Fluvoxamine and fluoxetine pose the greatest risk of pharmacokinetic interactions through CYP2C9 inhibition, reducing the

clearance of warfarin's active *S*-enantiomer. However, increased bleeding times with SSRIs alone or in combination with anticoagulants or nonsteroidal anti-inflammatory drugs also may be possible as a result of depleting platelets of serotonin and attenuating their aggregation ([Pollock et al. 2000b](#); [Shin et al. 2015](#)).

At present, there is only limited evidence that genetic differences may influence pharmacodynamics in older patients. Depressed elderly patients with the long-long (LL) serotonin transporter promoter genotype were found to have a more rapid initial response to paroxetine ([Pollock et al. 2000a](#)). This is consistent with results obtained with other SSRIs in younger patients ([Serretti et al. 2006](#)). Another study in geriatric major depression found that carriers of the short (S) allele experienced more severe adverse events during paroxetine treatment ([Murphy et al. 2004](#)). Interestingly, findings in Koreans with late-life depression were in the opposite direction—that is, better responses among carriers of the S allele ([Kim et al. 2006](#)).

---

## **Antidepressants in the Elderly**

---

### **Treatment of Late-Life Depression**

The combined prevalence of major depressive disorder and dysthymia in late life is 5%–12% in epidemiological studies; this rate is similar to the rate in the younger adult population. However, the symptom pattern and frequency of specific depressive subtypes appear to be different; older patients have more somatic symptoms, and both the melancholic and the delusional subtypes of depression

increase in frequency in older populations. In addition, some degree of cognitive impairment, whether manifesting only concurrently with the depressive episode or as a function of age, is common.

As in younger patients, untreated depression in late life causes significant social, vocational, and interpersonal morbidity, and depression in late life is associated with a significant risk of mortality. Comorbid depression adversely affects the course of several disease processes; this has been best documented for ischemic heart disease. Patients with unstable angina, post-myocardial infarction, or congestive heart failure who are depressed have a higher cardiac mortality rate than do medically comparable patients who are not depressed ([Musselman et al. 1998](#)). Furthermore, the suicide rate in men (in the United States, specifically white men) increases dramatically after age 60 years and continues to rise significantly as a function of age.

## Studies of Antidepressant Treatment in Older Patients

Considering the physiological changes associated with aging and the differences in the phenomenology and possible etiology of depression in late life compared with earlier in life, it is expected that clinical trials of antidepressants in late life will have a unique set of patient moderators and study design mediators that may significantly affect results. Variability in results of randomized controlled trials of antidepressants in late-life depression may result from heterogeneity in the patient population. Treatment moderators that have been identified as significant for late-life depression include the following:

- Subtype (e.g., melancholic or atypical)
- Severity
- Medical burden
- Social support
- Abnormalities on magnetic resonance scans indicating vascular disease
- Pattern of neurocognitive abnormalities labeled “executive dysfunction”

With respect to mediators of treatment response, the standard considerations in study design—namely, randomization, placebo versus comparator control, dosage, duration, and criteria for response and remission—are all important, but specifically the value of placebo-controlled trials versus comparator trials and optimal duration of treatment have been systematically reexamined. [Sneed et al. \(2008\)](#) conducted a meta-analysis of all studies published in peer-reviewed journals from 1985 to 2006 that were randomized placebo-controlled or comparator (a comparison of two active conditions) trials of antidepressants for the treatment of late-life depression. The intent of the meta-analysis was to determine whether rates of response to medications in comparator trials are significantly higher than rates of response to comparable medications in placebo-controlled trials—that is, whether study design significantly affects treatment outcome. Sixteen studies (9 comparator trials and 7 placebo-controlled trials) met the rigorous inclusion criteria for the meta-analysis. As hypothesized, antidepressant response rates were significantly higher in the comparator trials compared to placebo-controlled trials; the estimated probability of antidepressant response in a placebo-controlled trial was 46% as compared with 60% in a

comparator trial. One possible explanation for the higher response rate to the same medication in a comparator trial is that patient, doctor, and even research rater expectations of response are higher when it is known that the subject is receiving an active medication. Irrespective of the reason that response rates are higher in comparator trials, the results of the study suggest that when clinicians want to make evidence-based treatment decisions and communicate likelihood of response to patients, data from comparator trials may be more appropriate than results of placebo-controlled trials, since comparator trials more closely approximate the clinical situation in that both patient and doctor know that an active medication is being prescribed.

## Tricyclic Antidepressants

Most of the placebo-controlled trials involving TCAs were done before the use of plasma-level measurements to ensure optimal TCA treatment. Later randomized controlled trials that compared TCAs with SSRIs were invariably supported by the pharmaceutical industry, which had no desire to compare their new compound against optimal TCA treatment. Consequently, the preponderance of studies of TCA treatment in late-life depression reported inadequate dosages of the tertiary-amine TCAs amitriptyline and imipramine. Nonetheless, the results of these studies established that TCAs are an effective treatment for depression in geriatric patients.

**Nortriptyline.** Of the TCAs, nortriptyline has been found to induce the least orthostatic hypotension and has a documented “therapeutic window” that permits optimal dosing ([Roose et al. 1981](#)). Consequently, nortriptyline has

emerged as the choice of this class of medications issued to treat late-life depression. However, there are no rigorous placebo-controlled trials of nortriptyline in late-life depression; thus, the relative effectiveness of this medication is inferred from two open trials and three randomized comparator trials.

In a study reported by [Flint and Rifat \(1996\)](#), 101 patients meeting DSM-III-R ([American Psychiatric Association 1987](#)) criteria for major depressive disorder were treated openly with nortriptyline. The dosing schedule was as follows: all patients achieved a daily dosage of 75 mg by the end of week 1, and then the dosage was adjusted if necessary to achieve a plasma level within the therapeutic window of 50–150 ng/mL. The treatment duration was 6 weeks, and the remission criterion was a final Hamilton Rating Scale for Depression (Ham-D; 17-item) score of 10 or less; 60% of the intent-to-treat sample and 75% of the completers met the remission criterion. To establish speed of response, the authors determined the week of treatment that the 61 patients who met the criterion for remission at the end of the study first achieved sustained remission. Not surprisingly, at the end of week 1, no patient met the criterion for remission, and thus the cumulative response rate was 0%. At week 2, 11% of the sample met the remission criterion, and at week 3, 33% met the remission criterion (thus, the cumulative rate at the end of week 3 was 11%+33%, or 44%). At weeks 4 and 5, 25% and 20%, respectively, met the remission criterion. Thus, the accumulated remission rate at the end of week 5 was 89%. Although it is widely believed that late-life depression patients should have longer treatment trials, specifically 12 weeks, this study found that 89% of the patients who eventually recovered did so by the end of week 5. A second

open study of a therapeutic plasma level of nortriptyline reported on 42 inpatients (mean age: 70 years) with cardiac disease and melancholic depression who also were treated for 6 weeks ([Roose et al. 1994](#)). The remission criterion was a final Ham-D (21-item) score of 8 or less; the intent-to-treat remission rate was 67%, the completer remission rate was 82%, and the dropout rate was 19%.

Three randomized controlled trials compared nortriptyline with an SSRI; two studies compared a therapeutic plasma level of nortriptyline with paroxetine, and one study compared flexible-dose nortriptyline with sertraline. [Mulsant et al. \(2001a\)](#) compared nortriptyline with paroxetine in 116 inpatients and outpatients (mean age: 72 years) in a 12-week trial. Patients were considered to be in remission if the final Ham-D (17-item) score was 10 or less; the intent-to-treat remission rate was 57% for the nortriptyline group and 55% for the paroxetine group. The rate of dropout due to side effects in the nortriptyline group was significantly higher than that in the paroxetine group (33% vs. 16%;  $P=0.04$ ).

A second randomized controlled trial comparing nortriptyline (targeted to a therapeutic plasma level) with paroxetine is included in this chapter, although technically it should not be considered a geriatric study because the mean age of the patients was 58 years ([Nelson et al. 1999](#)). However, it is the only other study comparing a therapeutic plasma level of a TCA with an SSRI, and the results are consistent with those of the [Mulsant et al. \(2001a\)](#) study. In this trial, 81 outpatients with ischemic heart disease were treated with medication for 6 weeks. The remission criterion was a final Ham-D (17-item) score of 8 or less; in the intent-to-treat analysis, 63% of the nortriptyline group and 61% of the paroxetine group were remitters. The

dropout rate for nortriptyline (35%) was significantly higher than the dropout rate for paroxetine (10%) ( $P<0.05$ ). The rate of remission in study completers was 85% for nortriptyline and 68% for paroxetine, which was not a statistically significant difference, although the power of this comparison was limited by the small size of the completer group.

The randomized controlled trial comparing sertraline with nortriptyline included 210 patients (mean age: 68 years) randomly assigned to 12 weeks of medication treatment ([Bondareff et al. 2000](#)). This study did not report remission rates but only response rates, defined as a 50% reduction in Ham-D (24-item) score from baseline. The response rates for nortriptyline and sertraline were 41% and 52%, respectively.

**TCA side effects and safety.** Unfortunately, despite their robust effectiveness, the clinical utility of TCAs in the late-life population is limited by their side-effect and safety profiles. TCAs have significant anticholinergic effects that result in dry mouth, constipation, urinary retention, and confusional states.

The major safety problem with respect to the TCAs is cardiovascular effects ([Glassman et al. 1993](#)). TCAs are lethal in overdose, and as little as three times the daily dosage can result in death from heart block or arrhythmias. The TCAs have type 1A antiarrhythmic activity similar to that of moricizine and quinidine and consequently are presumed to confer an increased risk of sudden cardiovascular death if given to patients with ischemic heart disease. Given the prevalence of occult and manifest ischemic heart disease in both men and women older than

60 years, the use of TCAs in this population must reflect a careful consideration of the risk-benefit ratio.

## Selective Serotonin Reuptake Inhibitors

As in younger depressed patients, the SSRIs are the most prescribed class of antidepressants for late-life depression. Within this class, the various SSRIs appear to have equivalent efficacy and side-effect profiles. There are differences in pharmacokinetics and potential for drug-drug interactions, which are of importance in the geriatric population and have been discussed earlier in this chapter.

**Fluoxetine.** Four large studies of fluoxetine in late-life depression have been conducted: 1) a placebo-controlled study; 2) a three-cell study comparing venlafaxine, placebo, and fluoxetine; 3) a randomized controlled trial with a comparator drug; and 4) open treatment. In the first study, fluoxetine was compared with placebo in 671 patients ([Tollefson et al. 1995](#)). The dosing schedule was fluoxetine 20 mg/day for 6 weeks, and the remission criterion was a Ham-D (17-item) score of 7 or less after 4 weeks. The intent-to-treat analysis remission rate was 23% for fluoxetine and 13% for placebo; in the completer analysis, the remission rate was 27% for fluoxetine and 16% for placebo. Although fluoxetine was significantly more effective than placebo in both the intent-to-treat and the completer analyses, this was the first large SSRI trial in a geriatric population, and in comparison to the clinical experience with therapeutic plasma levels of TCAs, the remission rates in this study were disappointingly low.

In the comparator randomized clinical trial, patients were randomly assigned to receive either fluoxetine 20–40 mg/day or sertraline 50–100 mg/day for 12 weeks

([Newhouse et al. 2000](#)). The sample of 225 patients (mean age: 68 years) was somewhat unusual because the mean duration of the current episode of major depression was 9 years. The intent-to-treat remission rate was 46% for fluoxetine and 45% for sertraline, the completer remission rate was 60% for fluoxetine and 59% for sertraline, and the dropout rate was 33% for fluoxetine and 32% for sertraline. This study also reported an intriguing analysis of the response pattern of a subsample of 75 patients (42 treated with sertraline, 33 treated with fluoxetine) with a mean age of 75 years. For both sertraline and fluoxetine, 95% of the patients who achieved a 50% reduction in baseline Ham-D score did so by the end of week 8. As with the [Flint and Rifat \(1996\)](#) study of a therapeutic plasma level of nortriptyline, these data challenge the clinical wisdom that antidepressant trials in late-life depression must be extended to 12 weeks.

Finally, 308 patients meeting DSM-III ([American Psychiatric Association 1980](#)) criteria for major depressive disorder (mean age: 66 years) were treated openly with 20 mg/day of fluoxetine for 8 weeks ([Mesters et al. 1992](#)). The remission criterion was a final Ham-D (24-item) score of 10 or less; the intent-to-treat remission rate was 35%, the completer remission rate was 50%, and the dropout rate was 29%.

**Sertraline.** In addition to the two randomized controlled comparator trials previously described, nortriptyline versus sertraline and fluoxetine versus sertraline, a large rigorous placebo-controlled trial of sertraline in late-life depression was completed ([Schneider et al. 2003](#)). In this study, 716 patients (mean age: 70 years) were randomly assigned to flexible-dosage sertraline (50–100 mg/day) or placebo in an

8-week clinical trial. The criterion for remission was a final Ham-D (17-item) score of 10 or less; the intent-to-treat remission rate was 29% in the sertraline group, compared with 23% in the placebo group ( $P<0.05$ ).

**Paroxetine.** In addition to the two previously described trials that compared nortriptyline at a therapeutic plasma level with paroxetine, and in which the intent-to-treat remission rates (final 17-item Ham-D score  $\leq 10$ ) were 55% and 61%, respectively, a third trial compared mirtazapine with paroxetine ([Schatzberg et al. 2002](#)). In this study, 255 patients (mean age: 72 years) were randomly assigned to receive mirtazapine 30–45 mg/day or paroxetine 30–40 mg/day in an 8-week clinical trial. The criterion for remission was a final Ham-D (17-item) score of 7 or less; the intent-to-treat remission rates were 38% for mirtazapine and 28% for paroxetine and were not statistically different.

**Citalopram and escitalopram.** Many of the studies of citalopram in a geriatric population included patients with depression and dementia or significant cognitive impairment; therefore, the results of these studies are not comparable to those of other antidepressant trials in late-life depression ([Gottfries 1996](#)). However, two studies have provided information on citalopram in this population; the first was a single-blind comparison between citalopram and a therapeutic plasma level of nortriptyline, and the second was a comparison of citalopram with placebo in depressed patients older than 75 years.

In the first study, 58 patients (mean age: 71 years) were randomly assigned to treatment with a citalopram dosage of 30–40 mg/day or a therapeutic plasma level of

nortriptyline in a 12-week clinical trial ([Navarro et al. 2001](#)). The criterion for remission was a final Ham-D (17-item) score of 7 or less; the intent-to-treat remission rates were 69% for citalopram and 93% for nortriptyline. The remission rates for both medications were strikingly high in comparison with those in other trials; whether this result derived from differences in patient population or in study design is not obviously apparent.

The second trial is unique in the literature because it is the only study to focus on treatment of depression in the “old-old.” In this study, 174 patients were randomly assigned to treatment with either citalopram 20–40 mg/day or placebo in an 8-week clinical trial ([Roose et al. 2002](#)). The population was 58% female, with a mean age of 80 years and a mean baseline Ham-D (24-item) score of 24. The intent-to-treat response rate (50% reduction from baseline Ham-D score) was 41% in the citalopram group and 39% in the placebo group. The sample was divided for secondary analyses into patients with “severe” and “not severe” depression, which were defined as being either above or below the mean Ham-D score, respectively. The “not severe” group had a baseline Ham-D score of 22 and included 47 patients randomly assigned to receive citalopram and 59 patients randomly assigned to receive placebo. The criterion for remission was a final Ham-D score of 10 or less. In this group, the intent-to-treat remission rate was 34% for citalopram and 41% for placebo. The “severe” patient group had a mean baseline Ham-D score of 28 and included 37 patients randomly assigned to citalopram and 31 patients randomly assigned to placebo. In this group, the intent-to-treat remission rate was 36% for citalopram and 19% for placebo ( $P<0.05$ ). Thus, citalopram was significantly more effective than

placebo in the “severe” patient population, but this difference resulted not from an increased efficacy of citalopram compared with “not severe” patients but rather from a decreased efficacy of placebo.

A third study—an 8-week randomized controlled trial—compared citalopram (flexible dosage of 10–20 mg/day) and venlafaxine (flexible dosage of 75–150 mg/day) in the treatment of late-life depression ([Allard et al. 2004](#)). The study included 151 patients (mean age: 73 years; 73% female) with a baseline Montgomery-Åsberg Depression Rating Scale (MADRS) score of  $27 \pm 4$ . The response rates for venlafaxine versus citalopram were 75% and 73%, respectively, and the remission rates were 19% and 23%, respectively. The differences between the response rates and the remission rates were quite striking; it is unusual to see such a differential.

There has been one randomized controlled trial of escitalopram in the treatment of late-life depression ([Kasper et al. 2005](#)). In this study, 517 patients (mean age: 75 years; 75% female; mean baseline MADRS score:  $28 \pm 4$ ) were randomly assigned to escitalopram (10 mg/day), fluoxetine (20 mg/day), or placebo. There was no significant difference in response rates across the three treatment conditions (response rates: escitalopram 46%, fluoxetine 37%, and placebo 47%).

**SSRI side effects and safety.** As a group of medications, the SSRIs have the same side-effect profile in older patients as in younger patients: specifically, gastrointestinal distress, agitation, insomnia, and sexual dysfunction. Discontinuation rates for SSRIs are not statistically different from the discontinuation rates

reported for a therapeutic plasma level of nortriptyline in the geriatric samples.

With respect to safety, the SSRIs offer a significant advantage over the TCAs. SSRIs are relatively benign in overdose ([Barbey and Roose 1998](#)) and do not have an effect on blood pressure, heart rate, cardiac conduction, or cardiac arrhythmias ([Glassman et al. 2002](#); [Roose et al. 1998](#)). SSRIs block the uptake of serotonin into platelets and significantly reduce platelet function. SSRIs are associated with upper gastrointestinal bleeding, intracerebral hemorrhage, and postoperative bleeding complications ([Musselman et al. 1998](#)).

## Other Antidepressants

**Venlafaxine.** One study reported meaningful information about venlafaxine in a geriatric population ([Schatzberg and Cantillon 2000](#)). In this 8-week randomized controlled clinical trial, 204 patients (mean age: 71 years) were randomly assigned to treatment with venlafaxine (75–225 mg/day), fluoxetine (20–60 mg/day), or placebo. Remission was defined as a Ham-D (24-item) score less than 8; the intent-to-treat remission rate was 42% for venlafaxine, 29% for fluoxetine, and 38% for placebo (no statistically significant differences). Significantly more patients treated with venlafaxine (27%) and fluoxetine (19%) discontinued study participation because of side effects than did those given placebo (9%) ( $P<0.05$ ). Cardiovascular measures, including heart rate and measures of cardiac conduction (including pulse rate, QRS, and QTc intervals), were assessed, and neither medication induced a significant change compared with placebo in any of these measures.

**Duloxetine.** There has been one randomized controlled trial of duloxetine for the treatment of late-life depression. In this study, 311 patients (mean baseline Ham-D score:  $22 \pm 4$ ) were randomly assigned in a 2-to-1 allocation favoring duloxetine ([Raskin et al. 2007](#)). The response and remission (final Ham-D score:  $\leq 7$ ) rates were significantly greater for duloxetine than for placebo (response rates: duloxetine 37%, placebo 27% [ $P < 0.001$ ]; remission rates: duloxetine 19%, placebo 15% [ $P = 0.002$ ]). However, as with many other trials of antidepressant medication for the treatment of late-life depression, the remission rates are distressingly low.

**Mirtazapine.** As previously discussed, in one randomized controlled comparator trial of mirtazapine versus paroxetine in a geriatric population, the intent-to-treat remission rates were 38% for the mirtazapine group and 28% for the paroxetine-treated patients ([Schatzberg et al. 2002](#)). In this study, the rate of discontinuation due to adverse events was similar in both groups: 33% for mirtazapine and 29% for paroxetine.

**Bupropion.** One randomized controlled comparator trial of bupropion versus paroxetine in late-life depression has been published, and this represents the only data available on bupropion in this population ([Weihs et al. 2000](#)). In this 6-week clinical trial, 100 patients (mean age: 70 years), with a baseline Ham-D (24-item) score of 27, were randomly assigned to treatment with either bupropion (100–300 mg/day) or paroxetine (10–40 mg/day). Rates of response (defined as a 50% reduction from baseline Ham-D score) in the intent-to-treat analysis were 71% in the bupropion group and 77% in the paroxetine group.

Remission data were not reported. Discontinuation rates were 17% in the bupropion group and 15% in the paroxetine group.

## **Antipsychotic Augmentation of Antidepressant Treatment**

The use of atypical antipsychotics as an augmentation strategy in adults whose symptoms have not responded to antidepressants has been shown to be effective in many placebo-controlled studies. Concerns have been raised about whether the same approach would be effective and safe in the late-life population. In a recently completed study involving 181 depressed patients older than 60 years who had not responded to an open trial of venlafaxine, patients were randomly assigned to receive the addition of either aripiprazole or placebo for a 12 weeks ([Lenze et al. 2015](#)). The response rate with aripiprazole augmentation was significantly higher than that with placebo (44% vs. 29%). Aripiprazole treatment was associated with akathisia and parkinsonism, but these side effects resolved if the medication was discontinued.

---

## **Antipsychotics in the Elderly**

---

No class of medication, including antipsychotics, is approved by the U.S. Food and Drug Administration (FDA) to treat psychosis or agitation in patients with dementia, although risperidone is approved in Germany and a few other countries for this purpose. Nonetheless, antipsychotics and other psychotropic medications are used widely in the management of dementia-related psychosis or

agitation because there are no treatment alternatives; evidence for the effectiveness of nonpharmacological behavioral approaches is limited and may apply mainly to patients with mild behavioral symptoms ([Brodaty and Arasaratnam 2012](#)).

In the elderly, antipsychotic use in neurodegenerative disorders exceeds antipsychotic use in schizophrenia because of the difference in disease prevalence rates ([Colenda et al. 2002](#)). In this population, the prevalence of schizophrenia remains below 1%, whereas the prevalence of dementia is approximately 2%–5% for people older than 60 years, and the prevalence increases to 15%–40% for people older than 85 years ([Thomas et al. 2001](#)). Psychosis and behavioral dyscontrol occur in the majority of patients with dementia during the course of illness ([Devanand et al. 1997](#); [Lyketsos et al. 2000](#)). Consequently, use of antipsychotics is greater in elderly patients with dementia (prescribed off-label) than in those with schizophrenia.

## Special Safety Considerations in Older Patients

### **Antipsychotic Side Effects**

Older patients are more sensitive to the side effects of antipsychotics, which can include sedation, cardiac effects (e.g., tachycardia, orthostatic hypotension), anticholinergic side effects (e.g., dry mouth, blurred vision, constipation, urinary retention), neuroleptic malignant syndrome with hyperpyrexia, autonomic instability and tachycardia, pigmentary retinopathy, weight gain and associated

metabolic changes, allergic reactions, and seizures ([Arana 2000](#)).

The antipsychotics most likely to cause orthostatic hypotension are low-potency conventional (or typical) antipsychotics such as chlorpromazine and thioridazine and the atypical antipsychotics clozapine, risperidone, olanzapine, and quetiapine ([Tandon 1998](#)). Low-potency conventional antipsychotics and clozapine have the greatest potential to cause anticholinergic effects. At comparable dosages, low-potency conventional antipsychotics are less likely than high-potency conventional antipsychotics such as haloperidol to cause extrapyramidal side effects (EPS), but up to 50% of patients 60–80 years of age receiving conventional antipsychotics develop either EPS or tardive dyskinesia (TD) ([Jeste et al. 1999](#)). [Saltz et al. \(1991\)](#) reported an incidence of TD of 31% after 43 weeks of conventional antipsychotic treatment in a sample of elderly patients, and antipsychotic-induced TD is five to six times more prevalent in elderly than in younger patients ([Jeste 2000](#)). The susceptibility of older patients to the side effects of typical antipsychotics, particularly the neurological side effects of EPS and TD, requires the use of dosages lower than those commonly used in young adults. Atypical antipsychotics have a lower potential for TD compared with typical antipsychotics ([Jeste 2000](#)).

To varying degrees, the metabolic syndrome with glucose dysregulation is a potential side effect of all antipsychotic medications. New-onset type 2 diabetes mellitus or diabetic ketoacidosis may be more common with clozapine and olanzapine compared with other antipsychotics, and blood glucose levels need to be monitored in elderly patients ([Jin et al. 2004](#)). Weight gain is a problematic side effect of

several antipsychotics, particularly olanzapine and clozapine.

Sedation is one of the most common side effects of antipsychotic medications, with low-potency conventional antipsychotics being potent sleep inducers. In addition, low-potency antipsychotics have a greater propensity to cause anticholinergic side effects, which can lead to daytime confusion and disorientation in the elderly.

An Ontario, Canada, study that examined the medical records of 97,777 patients found an association between antipsychotic use and abnormal kidney function tests, although the mechanism underlying this effect was not clear ([Hwang et al. 2014](#)). There have been reports of an association between antipsychotic use and deep vein thrombosis in patients with dementia, which may be related to the decrease in mobility that is a common side effect of several antipsychotics ([Parker et al. 2010](#)).

Elderly patients are often taking a large number of medications, and drug interactions need to be considered when prescribing antipsychotics. Specifically, adding fluoxetine to risperidone raises risperidone levels ([Bondolfi et al. 2002](#)), and similar effects have been reported when fluoxetine is combined with typical antipsychotics ([Solai et al. 2001](#)).

## **Antipsychotic Mortality Risks**

The use of antipsychotics is associated with an increased risk of sudden cardiac death ([Ray et al. 2001](#)). Among the antipsychotics, thioridazine appears to carry the highest risk of sudden unexplained death that is believed to be due to cardiac causes ([Reilly et al. 2002](#)). Risperidone prolongs the QTc interval but has no effect on QT dispersion ([Yerrabolu et al. 2000](#)). Prolongation of the QTc interval,

which is associated with the development of torsades de pointes and sudden death, is known to occur with several antipsychotics, including the atypical antipsychotic ziprasidone, but aripiprazole may reduce the QTc interval ([Goodnick et al. 2002](#)).

Based on a review of double-blind, placebo-controlled trials of atypical antipsychotics in patients with dementia, the FDA concluded that there was a significantly greater mortality risk (1.6–1.7 times) for patients treated with these medications compared with those treated with placebo, and that all antipsychotic medications must carry a black box warning to this effect ([Jeste et al. 2008](#); [Schneider et al. 2005](#)). There is no clear explanation as to why the use of atypical antipsychotics is associated with an increased mortality risk in patients with dementia. There may be a small increase in the risk of stroke ([Brodaty et al. 2003](#)), but the increase in stroke risk does not by itself account for the increased mortality risk ([Jeste et al. 2008](#)). In a large-scale medical records study involving more than 75,000 nursing home patients receiving antipsychotics, haloperidol was associated with the greatest increase in mortality risk, risperidone and olanzapine with intermediate risk, and quetiapine with the lowest increase in mortality risk ([Huybrechts et al. 2012](#)). In a large U.S. Department of Veterans Affairs (VA) study, the association between antipsychotic use and mortality was highest for haloperidol, with the caveat that some patients receiving higher dosages of haloperidol were being treated for delirium, which may have artificially increased the mortality rate observed because of the known association between delirium and increased mortality ([Maust et al. 2015](#)). Another review suggested that the mortality risk associated with antipsychotics may not be as large as believed, possibly

because the FDA black box warning has led to a decrease in antipsychotic prescribing for elderly patients with dementia who also have serious medical illness ([Hulshof et al. 2015](#)).

## **Pharmacokinetic and Pharmacodynamic Issues**

Age-related decreases in gut motility and the anticholinergic effects of antipsychotics may decrease absorption rates. Antipsychotic drugs undergo biotransformation primarily in the liver, with the gastrointestinal tract, lungs, and kidneys being secondary sites. Antipsychotics have slightly longer half-lives in the elderly than in the rest of the adult population, thereby prolonging side effects ([Hicks and Davis 1980](#)). The concomitant use of antacids may lower antipsychotic blood levels ([Fann et al. 1973](#)).

Dopamine neurons degenerate with aging, particularly after age 70 years, and decreases in the number of cholinergic receptors occur in Alzheimer's disease ([Davies and Maloney 1976](#); [Perry et al. 1977](#)). The decrease in the number of available dopaminergic receptors reduces the tolerance of elderly patients to antipsychotics, thus increasing the likelihood of neurological side effects, including EPS and TD.

Blockade of dopamine type 2 (D<sub>2</sub>) receptors is believed to be the primary mechanism of action of antipsychotics. Atypical antipsychotics are more potent antagonists at the serotonin type 2A (5-HT<sub>2A</sub>) receptor than at the D<sub>2</sub> receptor, resulting in fewer EPS and less TD compared with typical antipsychotics ([Jeste et al. 1999](#)).

# Antipsychotics in Management of Behavioral Complications of Dementia

Patients with dementia often develop behavioral disturbances (e.g., agitation, aggression) or psychotic features (e.g., delusions, hallucinations). As used here, the term *behavioral complications* denotes both behavioral disturbances and psychotic features. Behavioral complications occur in most forms of dementia, lead to considerable burden for caregivers, and are common precipitants of institutionalization.

Personality changes occur early in dementia and include apathy, anhedonia, irritability, inability to pay attention, depression, and loss of emotional connection ([Rubin and Kinscherf 1989](#)). In later stages, varying degrees of agitation may occur in more than half of Alzheimer's disease patients in outpatient clinics ([Devanand et al. 1997](#)) and nursing homes ([Cohen-Mansfield et al. 1989](#)), with aggressive behavior also becoming common ([Devanand et al. 1997](#); [Swearer et al. 1988](#)). Other disinhibited behaviors include pacing, wandering, verbal and physical aggression, repetitive calling out and screaming, and (rarely) self-mutilating behaviors. Catastrophic reactions, including bursts of anger and even violent behavior, can occur when patients are required to perform tasks beyond their cognitive capacities ([Devanand et al. 1992a](#)). Stubbornness, or refusal to complete essential activities of daily life, can be particularly frustrating for caregivers.

The prevalence of delusions ranges from 0% to 50% in different samples of Alzheimer's disease patients

([Devanand et al. 1997](#); [Lyketsos et al. 2000](#); [Reisberg et al. 1989](#)). Isolated delusional thoughts are more common than diagnosable psychotic disorders, and paranoid delusions of theft and suspicion are the most frequent types of delusions. Systematized complex delusions and grandiose delusions are relatively rare in Alzheimer's disease and other dementias. Delusional processes in dementia can be chronic or intermittent, a feature that distinguishes them from delusions in schizophrenia. Hallucinations, which can be visual or auditory, occur in 5%–15% of patients with dementia. In Alzheimer's disease, a typical hallucination is the conviction that someone else is in the house (i.e., phantom boarder syndrome). Diagnostic criteria for psychosis in Alzheimer's disease have been developed ([Jeste and Finkel 2000](#)).

In a series of 235 patients with mild to moderate Alzheimer's disease who were followed prospectively for up to 5 years, approximately half of the patients who manifested paranoid delusions or hallucinations at baseline were likely to manifest the same symptom 6 months later ([Devanand et al. 1997](#)), a finding consistent with other reports ([Ballard et al. 1997](#); [Paulsen et al. 2000](#)). However, paranoid delusions or hallucinations were evident at three out of four consecutive visits (over a period of 2 years) in only 10%–15% of patients, which raises the question of how long patients need to continue taking antipsychotics after treatment response. Psychosis and behavioral dyscontrol often coexist in Alzheimer's disease, and treatment with antipsychotics is often prescribed for one or both sets of symptoms.

## **Assessment of Psychopathology in Alzheimer's Disease**

In elderly patients, assessment and treatment of psychopathology should occur after reversible medical conditions (e.g., occult urinary tract infection, metabolic imbalance, iatrogenic or medication-induced symptoms) have been ruled out. Because of the impairment induced by Alzheimer's disease and other dementias, most rating scales have been developed as informant-based interviews. Commonly used rating scales for measurement of neuropsychiatric symptoms of Alzheimer's disease include the Neuropsychiatric Inventory (NPI; [Cummings et al. 1994](#)), the Neuropsychiatric Inventory—Nursing Home Version ([Wood et al. 2000](#)), the Behavioral Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD; [Reisberg et al. 1987](#)), the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) Behavior Rating Scale ([Tariot et al. 1995](#)), the Cohen-Mansfield Agitation Inventory (CMAI; [Cohen-Mansfield et al. 1989](#)), and the Columbia University Scale for Psychopathology in Alzheimer's Disease (CUSPAD; [Devanand et al. 1992b](#)). The NPI, which uses a quantitative time-efficient decision-tree approach, is the most widely used scale for evaluating the effects of antipsychotic treatment in patients with dementia. Recently, international consensus criteria were developed for the syndrome of agitation in dementia and other neurocognitive disorders in older adults, and these criteria are being used in treatment trials for agitation in dementia, including the most common form, Alzheimer's disease ([Cummings et al. 2015](#)).

## **Neurobiological Mechanisms of Psychosis in Dementia**

Alzheimer's disease patients with psychosis have been found to have significantly more plaques and tangles in the medial temporal-prosubicular area and the middle frontal cortex (Zubenko et al. 1991) and four to five times higher levels of abnormal paired helical filament (PHF)-tau protein in the entorhinal and temporal cortices (Mukaetova-Ladinska et al. 1993). A decrease in serotonin in the prosubiculum of the cerebral cortex has been reported in patients with psychotic compared with nonpsychotic dementia (Lawlor et al. 1995; Zubenko et al. 1991). Decreases in acetylcholine have been correlated with increases in thought disorder (Sunderland et al. 1997). Cholinergic agents, including the acetylcholinesterase inhibitors (donepezil, rivastigmine, galantamine) that are used to treat cognitive impairment in Alzheimer's disease, may also reduce behavioral symptoms (Bodick et al. 1997; Kaufer et al. 1996; Raskind 1999). Higher levels of norepinephrine in the substantia nigra (Zubenko et al. 1991) and higher levels of  $\beta$ -adrenergic receptors (Russo-Neustadt and Cotman 1997) in multiple brain regions have been reported in psychotic compared with nonpsychotic patients with Alzheimer's disease. These data suggest an enhanced responsiveness of catecholamines that may be associated with increased psychosis in Alzheimer's disease (Peskind et al. 1995). Homozygosity of the 1 and 2 alleles of the dopamine receptor *DR3* gene (Holmes et al. 2001; Sweet et al. 1998) and homozygosity for the C102 allele of the 5-HT<sub>2A</sub> receptor gene (Nacmias et al. 2001) may be associated with psychosis in Alzheimer's disease. However, the precise pathophysiology underlying psychosis in Alzheimer's disease is still unknown.

## Psychotropic Medication Use in Dementia

Studies in the 1970s and early 1980s indicated that nearly half of inpatients with dementia in VA hospitals ([Prien et al. 1975](#)) and in other settings ([Michel and Kolakowska 1981](#)) received psychotropic medications, primarily antipsychotics and benzodiazepines ([Ray et al. 1980](#)). Growing awareness of the neurological side effects of typical antipsychotics, particularly in dementia patients in nursing homes, led to the promulgation of the Omnibus Budget Reconciliation Act (OBRA) of 1987 ([Elon and Pawlson 1992](#)), which became effective in 1990. OBRA required identification of target symptoms, justification for the use of antipsychotics, and mandatory attempts to decrease or stop the antipsychotic medication every 3 months. Nonetheless, antipsychotic medications have remained the treatment of choice for behavioral complications in dementia ([Devanand et al. 1998](#); [Katz et al. 1999](#); [Schneider et al. 1990](#); [Street et al. 2000](#)), and drug utilization studies show that antipsychotics are used in 30%–50% of elderly institutionalized patients ([Giron et al. 2001](#); [Lantz et al. 1990](#)), although their use may have decreased in recent years after the FDA black box warning on increased mortality in patients with dementia receiving antipsychotics.

## **Studies of Antipsychotics in Dementia**

The results of a 1990 meta-analysis of placebo-controlled treatment trials indicated that typical antipsychotic treatment in dementia was significantly more efficacious than placebo, with the magnitude of the advantage over placebo averaging 18% ([Schneider et al. 1990](#)). In later placebo-controlled clinical trials with typical or atypical antipsychotics, response rates have varied between 45% and 60% for active medication and between 20% and 45% for placebo ([De Deyn et al. 1999](#); [Devanand et al. 1998](#);

Katz et al. 1999; Street et al. 2000), with an overall advantage for antipsychotic over placebo in the range of 18%–26% (Kindermann et al. 2002; Lanctôt et al. 1998). Clinically, a complete “cure” of the target psychotic and behavioral symptoms is uncommon.

In schizophrenia, antipsychotics are often assumed to be specific to the treatment of psychosis, and improvement in behavioral dyscontrol is believed to be secondary to improvement in psychosis. However, in patients with dementia, placebo-controlled studies consistently show comparable advantages for antipsychotics over placebo for symptoms of both psychosis and behavioral dyscontrol (Brodaty et al. 2003; De Deyn et al. 1999; Devanand et al. 1998; Katz et al. 1999; Street et al. 2000).

**Typical antipsychotics.** Early placebo-controlled studies of typical antipsychotics used in the management of behavioral complications of dementia showed moderate efficacy with a high placebo response rate, and considerable EPS occurred even at moderate dosages (Barnes et al. 1982; Finkel et al. 1995; Petrie et al. 1982; Rada and Kellner 1976). In a double-blind, placebo-controlled, randomized comparison of standard-dosage (2–3 mg/day) and low-dosage (0.50–0.75 mg/day) haloperidol in 71 outpatients with Alzheimer’s disease (Devanand et al. 1998), standard-dosage haloperidol was efficacious and superior to both low-dosage haloperidol and placebo for symptoms of both psychosis and agitation (Devanand et al. 1998). EPS tended to be greater for haloperidol (2–3 mg/day) than for the other two conditions. Low-dosage haloperidol did not differ from placebo on any measure of efficacy or side effects.

In another study that compared the SSRI citalopram, the typical antipsychotic perphenazine, and placebo, citalopram was comparable to perphenazine in efficacy and significantly superior to placebo, with an advantageous side-effect profile ([Pollock et al. 2002](#)).

**Atypical antipsychotics.** Because of their more favorable safety profile, the atypical antipsychotics have gradually replaced typical antipsychotics in the treatment of behavioral complications in dementia. Atypical antipsychotics can be safely administered with cholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine), which are used to treat the cognitive impairment of dementia ([Weiser et al. 2002](#)). The choice of atypical antipsychotic depends on the patient's clinical profile and the medication's side-effect profile (e.g., a patient prone to falls should receive a medication that is not likely to cause orthostatic hypotension). Clozapine, risperidone, paliperidone and iloperidone (risperidone metabolites), olanzapine, quetiapine, aripiprazole, ziprasidone, lurasidone, asenapine, and cariprazine are the atypical antipsychotics that are currently available. There are as yet no published studies examining ziprasidone, lurasidone, asenapine, or cariprazine in the treatment of psychosis or agitation in patients with dementia.

*Clozapine.* Clozapine was the first atypical antipsychotic to become available in the United States. Clozapine causes substantial serotonergic blockade and has antiadrenergic and antimuscarinic properties ([Lieberman 1998](#)). Clozapine may be more efficacious than other antipsychotics in schizophrenia, and it carries essentially no risk of TD ([Kane et al. 1988](#)). Circulating levels of clozapine rise with dosage

and age and may be slightly higher in women than in men; sedation is common, and seizure potential is elevated (Centorrino et al. 1994; Kurz et al. 1998). Clozapine's anticholinergic properties can lead to dry mouth and constipation and can adversely affect cognition in the elderly. Also, intensive monitoring is required for blood dyscrasias, particularly agranulocytosis, which is reported to occur in 0.38% of patients (Kane et al. 1988). These factors, as well as the increased risk of falls and fractures related to the side effect of orthostatic hypotension, limit the use of clozapine in the elderly. The few retrospective reviews and case reports available indicate moderate efficacy but significant adverse events, suggesting very low tolerability in elderly patients with dementia (Chengappa et al. 1995; Oberholzer et al. 1992; Pitner et al. 1995). Therefore, clozapine is rarely used in patients with dementia.

*Risperidone.* Risperidone has serotonin 5-HT<sub>2</sub> and dopamine D<sub>2</sub> blocking properties,  $\alpha_1$ - and  $\alpha_2$ -adrenergic blocking properties, minimal histaminergic (H<sub>1</sub>) blocking properties, and little affinity for cholinergic receptors (Janssen et al. 1988). Its elimination half-life is between 20 and 22 hours, allowing for once-a-day dosing (Byerly and DeVane 1996).

In young adults with schizophrenia, risperidone 6 mg/day has the best therapeutic profile compared with lower and higher dosages, with a low propensity for EPS (Chouinard et al. 1993). By contrast, the optimal risperidone dosage range is much lower for elderly patients (Katz et al. 1999). Compared with the other atypical antipsychotics, risperidone may be more likely to lead to EPS and TD, although its risk is still considerably lower than that

associated with typical antipsychotics such as haloperidol; in one study, risperidone's 1-year cumulative incidence of TD was a relatively low 2.6% in institutionalized patients with dementia ([Jeste et al. 2000](#)). Risperidone is mildly sedating and has the potential to cause orthostatic hypotension, although the latter effect is uncommon when low dosages are used in the elderly ([Katz et al. 1999](#)).

In a multicenter study, 625 nursing home patients (mean age: 83 years) with dementia (73% Alzheimer's disease, 15% vascular dementia, 12% mixed dementia; mean 30-item Mini-Mental State Examination [MMSE] score: 6.6) who had behavioral complications were randomly assigned to receive risperidone—at 0.5 mg/day, 1.0 mg/day, or 2.0 mg/day—or placebo for 12 weeks ([Katz et al. 1999](#)). At study endpoint, response rates for risperidone 1 mg/day (45%) and 2 mg/day (50%) were significantly superior to rates for placebo and risperidone 0.5 mg/day, which showed similar response rates (33%). Patients receiving risperidone 2 mg/day were more likely than those receiving risperidone 0.5 mg/day or 1 mg/day to develop EPS and sedation, suggesting a relatively narrow therapeutic window. Therefore, a risperidone starting dosage of 0.5 mg/day, with gradual upward dosage titration to 1–2 mg/day, is recommended. A meta-analysis of four placebo-controlled trials with risperidone found that it was superior to placebo in treating psychosis and agitation, particularly in severely disturbed patients ([Katz et al. 2007](#)). Although a long-acting injectable risperidone preparation is available, that formulation has not been studied in the treatment of behavioral complications of dementia.

Paliperidone and iloperidone are chemically related to risperidone and are approved for the treatment of schizophrenia ([Davidson et al. 2007](#); [Marder et al. 2007](#))

but have not been studied systematically in the treatment of behavioral complications in dementia.

*Olanzapine.* Olanzapine blocks multiple receptor sites, including serotonin 5-HT<sub>2A/2C</sub> and dopamine D<sub>4/3/2/1</sub> (serotonin-to-dopamine receptor binding ratio of 8:1), histaminergic H<sub>1</sub> receptors, muscarinic acetylcholine receptors, and noradrenergic  $\alpha_1$  receptors ([Bymaster et al. 1996](#)). Olanzapine is well absorbed and, is unaffected by food, and because of its mean half-life of 30 hours, it can be used once a day ([Fulton and Goa 1997](#)).

Sedation and weight gain are prominent side effects of olanzapine, and its use has been associated with the development of metabolic syndrome. Orthostatic hypotension is not common when low dosages are used in elderly patients ([Street et al. 2000](#)). Intramuscular olanzapine is a useful alternative to intramuscular haloperidol in the treatment of acutely psychotic, agitated patients with schizophrenia ([Breier et al. 2002a](#)) and may be a useful alternative to intramuscular lorazepam in patients with dementia ([Meehan et al. 2002](#)).

In a double-blind, placebo-controlled multicenter clinical trial, 206 nursing home patients (mean age: 83 years) with Alzheimer's disease (mean MMSE score: 6.9) and behavioral complications were randomly assigned to placebo or fixed-dosage olanzapine (5 mg/day, 10 mg/day, or 15 mg/day) for 6 weeks. Olanzapine 5 mg/day was significantly more efficacious than placebo, but the 10-mg/day and 15-mg/day dosages were not superior to placebo. The prominent side effects of sedation and weight gain were limiting factors at the higher dosages ([Street et al. 2000](#)). Clinically, a starting dosage of 2.5 mg/day with gradual upward titration is recommended.

*Quetiapine.* Quetiapine acts as an antagonist at multiple neurotransmitter receptors in the brain, including dopamine D<sub>1</sub> and D<sub>2</sub>, serotonin 5-HT<sub>1A</sub> and 5-HT<sub>2</sub>, histamine H<sub>1</sub>, and  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors. D<sub>2</sub> receptor affinity is less than 5-HT<sub>2</sub> receptor affinity. Quetiapine has no appreciable binding affinity at cholinergic muscarinic or benzodiazepine receptors (Casey 1996). Although it has a short half-life (approximately 3–6 hours; Fulton and Goa 1997), quetiapine's efficacy has been documented with twice-daily administration (McManus et al. 1999).

The incidence of EPS is very low with quetiapine. In a study of 284 elderly patients with dementia, quetiapine (average dosage 96.9 mg/day) and haloperidol (average dosage 1.9 mg/day) were indistinguishable from placebo on most measures of efficacy, although haloperidol led to more EPS (Tariot et al. 2006). The optimal dosage for quetiapine is undetermined because dosage comparison studies have not been conducted in patients with dementia. Wide dosage ranges (from 12.5 to 800 mg/day) are used in clinical practice. Physicians often prescribe quetiapine because of its relatively benign side-effect profile and to take advantage of its main side effect, sedation, in patients who have insomnia.

*Aripiprazole.* A placebo-controlled study of aripiprazole in 208 outpatients with behavioral complications of Alzheimer's disease showed no advantage for aripiprazole on the main outcome measure (NPI score), but there was superiority on secondary outcome measures (Brief Psychiatric Rating Scale [BPRS] psychosis and BPRS Core subscale scores). The average dosage used was 10 mg/day, which was generally well tolerated (De Deyn et al. 2005).

These limited data suggest that aripiprazole has a role as a second-line atypical antipsychotic treatment in Alzheimer's disease patients with behavioral complications and that low starting dosages of 2–5 mg/day can be used.

**Comparisons among antipsychotics.** Head-to-head comparison studies have shown few differences between typical antipsychotics in the treatment of behavioral complications in dementia ([Barnes et al. 1982](#); [Carlyle et al. 1993](#); [Petrie et al. 1982](#); [Smith et al. 1974](#); [Tsuang et al. 1971](#)).

In a study comparing a typical with an atypical antipsychotic, patients with dementia and behavioral complications were randomly assigned to receive flexible-dose risperidone, haloperidol, or placebo ([De Deyn et al. 1999](#)). In 344 patients, risperidone (average dosage: 1.1 mg/day), haloperidol (average dosage: 1.2 mg/day), and placebo produced improvement rates of 54%, 63%, and 47%, respectively, at week 12 ( $P=0.25$ ). No significant differences in improvement were seen between the groups on psychosis scores. In post hoc analyses, both haloperidol and risperidone were significantly better than placebo in reducing BEHAVE-AD total scores and CMAI aggression cluster scores ( $P=0.01$ ), and risperidone was superior to haloperidol on the CMAI aggression cluster score ( $P=0.05$ ). Patients taking haloperidol had significantly higher EPS scores at endpoint than did patients taking either risperidone or placebo, with no significant difference in EPS scores between patients receiving risperidone and those receiving placebo ([De Deyn et al. 1999](#)). Overall, risperidone's efficacy was comparable to that of haloperidol, but with a superior side-effect profile. In smaller studies in patients with dementia, comparisons of

haloperidol and risperidone have yielded equivocal results ([Chan et al. 2001](#); [Suh et al. 2004](#)).

In adults with schizophrenia, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) showed only marginal superiority in antipsychotic effectiveness for olanzapine compared with typical and other atypical antipsychotics ([Lieberman et al. 2005](#)). In England, the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS) of 227 patients with schizophrenia did not show any differences in treatment response for atypical versus typical antipsychotics ([Jones et al. 2006](#)).

In the 421 elderly patients who participated in the Clinical Antipsychotic Trials of Intervention Effectiveness-Alzheimer's Disease (CATIE-AD), which compared risperidone, olanzapine, quetiapine, and placebo (first randomized phase), there were no significant differences in time to discontinuation because the superior efficacy of risperidone and olanzapine was compromised by their increased propensity to side effects; quetiapine was indistinguishable from placebo ([Schneider et al. 2006](#)). These findings indicate that efficacy must be weighed against side effects when prescribing risperidone or olanzapine in a patient with dementia and that quetiapine may not be as effective.

**Comparisons of antipsychotics versus benzodiazepines.** The few early studies that compared antipsychotics with benzodiazepines suffered from methodological flaws, particularly in sample selection and study design ([Burgio et al. 1992](#); [Covington 1975](#); [Kirven and Montero 1973](#); [Stotsky 1984](#); [Tewfik et al. 1970](#)). The data available from these studies did not indicate superiority for benzodiazepines over antipsychotics in the

treatment of behavioral complications in patients with dementia.

Benzodiazepines are known to have deleterious effects on learning and memory both in healthy younger subjects ([Ghoneim et al. 1981](#); [Jones et al. 1978](#); [Liljequist et al. 1978](#)) and in the elderly, even without baseline cognitive impairment ([Pomara et al. 1991, 2015](#)). Benzodiazepines can lead to tolerance and dependence, and worsening of cognition is a concern. Therefore, benzodiazepines should be used at low dosages, and use should be restricted to short-term crisis management of agitated and anxious behaviors if antipsychotics or other medications are ineffective.

**Studies of anticonvulsants and other agents.** A small-sample study by [Tariot et al. \(1998\)](#) suggested that carbamazepine was effective in the treatment of behavioral complications of Alzheimer's disease, and there were suggestions that valproate was efficacious in a single-site study by the same research group ([Porsteinsson et al. 2001](#)). However, valproate at an average dosage of 800 mg/day did not show superiority over placebo in a larger study of 153 nursing home patients who participated in a double-blind, placebo-controlled trial ([Tariot et al. 2005](#)). Nonetheless, anticonvulsants such as valproate are routinely prescribed in nursing homes.

Studies of other medications, such as buspirone ([Lawlor et al. 1994](#)), trazodone ([Sultzer et al. 1997](#); [Teri et al. 2000](#)), lithium ([Holton and George 1985](#)), and propranolol ([Shankle et al. 1995](#); [Weiler et al. 1988](#)), have involved case series or small samples, usually without placebo controls. These medications can be considered as therapeutic options only after antipsychotic treatment has failed.

In a 12-week placebo-controlled trial in patients with dementia and agitation, citalopram showed a small but significant advantage over placebo in some but not all measures of efficacy ([Porsteinsson et al. 2014](#)). However, the majority of patients received citalopram 30 mg/day, which is higher than the FDA dosage limit of 20 mg/day, which was instituted because of QT prolongation on the electrocardiogram at higher dosages.

## Choice of Antipsychotic

The potential side-effect profile should determine the choice of antipsychotic for individual patients ([Ellingrod et al. 2002](#)). Clozapine should be reserved for those patients who do not respond to the other available antipsychotics. Patients prone to orthostatic hypotension (e.g., patients receiving  $\beta$ -blockers) may develop this side effect while taking risperidone or olanzapine, although postural hypotension is uncommon at low dosages ([Katz et al. 1999](#); [Street et al. 2000](#)). Olanzapine causes weight gain and is strongly sedating, but the latter side effect may be advantageous in patients with prominent insomnia. The metabolic syndrome can occur with all antipsychotics but is most likely to occur with olanzapine. Quetiapine is generally well tolerated, but it can be sedating. Among the atypical antipsychotics, risperidone is the most likely to cause EPS, so olanzapine or quetiapine should be preferred in elderly patients who have parkinsonian features. The incidence of TD is much lower with atypical antipsychotics than with the typical antipsychotic haloperidol ([Jeste et al. 2000](#)). In a study of 35 agitated patients with dementia who were switched from haloperidol to risperidone, the crossover was generally safe and effective ([Lane et al. 2002](#)). Overall, the decreased likelihood of neurological side effects, both short-

term and long-term, makes atypical antipsychotics the treatment of choice in these patients.

### **Optimal Antipsychotic Dosing Strategy**

The studies with haloperidol and risperidone produced similar results: very low dosages were ineffective, whereas high dosages led to side effects, suggesting a relatively narrow therapeutic window for these medications in dementia patients who develop behavioral complications. The optimal dosage for olanzapine appears to be 5 mg/day, based on the study comparing 5, 10, and 15 mg/day ([Street et al. 2000](#)). The optimal quetiapine dosage remains uncertain.

In patients with Alzheimer's disease, risperidone should be started at 0.25–0.50 mg/day at bedtime (or twice-daily dosing), with a 0.5-mg/day increase per week to a maximum of 2 mg/day (or possibly 3 mg/day). Olanzapine should be started at 2.5 mg/day or 5.0 mg/day at bedtime and slowly increased to a target daily dosage of 5–10 mg. Quetiapine should be started at 25 mg twice daily, with dosage increases as tolerated up to 300 mg twice daily, based solely on clinical response and side effects, because the optimal dosage range for quetiapine has not been identified. If a typical antipsychotic is used, a starting dosage equivalent to haloperidol 0.5 mg/day is advisable, with subsequent individualized titration to achieve an optimal trade-off between efficacy and side effects.

### **Use of Concomitant Psychotropics**

Use of anticholinergic agents to treat EPS should be avoided, particularly in Alzheimer's disease, in which a cholinergic deficit is believed to underlie much of the

cognitive impairment. In some patients, concomitant use of a hypnotic (e.g., zolpidem 5-10 mg/day or zaleplon 5-10 mg/day) may be required. Trazodone at dosages of 25-200 mg/day can also be used as a hypnotic in these patients. As noted earlier, benzodiazepine use should be limited to short-term crisis management of anxiety or agitation.

## **Optimal Duration of Antipsychotic Treatment**

A trial of 6-12 weeks usually is sufficient to determine the outcome of an antipsychotic treatment trial. If the optimal antipsychotic dosage is reached quickly, clinical response may occur within the first 1 or 2 weeks. On the other hand, the need to adjust the dosage because of side effects may require a relatively prolonged trial period.

The expected natural course of target symptoms during the course of dementia should be considered in determining the duration of antipsychotic treatment. Delusions and hallucinations are not very persistent, whereas agitation usually persists for several months to years during the course of Alzheimer's disease ([Devanand et al. 1997](#)).

Conflicting evidence exists regarding how long antipsychotic medications should be continued in these patients. One report suggested that antipsychotics and other psychotropics can be discontinued in nursing home patients with dementia without increased risk of behavioral symptom relapse ([Cohen-Mansfield et al. 1999](#)), but other reports indicate a moderate to high rate of relapse after discontinuation ([Avorn et al. 1992](#); [Fitz and Mallya 1992](#); [Horwitz et al. 1995](#)). A British study suggested that antipsychotic withdrawal leads to a moderately increased risk of relapse ([Ballard et al. 2004](#)), but multiple

antipsychotics were withdrawn, and the results were not clear-cut.

In the largest study to examine relapse risk after antipsychotic discontinuation ([Devanand et al. 2012](#)), 180 Alzheimer's disease patients with psychosis or agitation/aggression received 16 weeks of open treatment with risperidone (mean dosage 0.97 mg/day). Responders were then randomly assigned, in a double-blind manner, to one of three arms: 1) continuation risperidone for 32 weeks, 2) risperidone for 16 weeks followed by placebo for 16 weeks, or 3) placebo for 32 weeks. In the initial open-label treatment phase, psychosis and agitation improved, with mild increases in EPS; 112 patients met criteria for response to treatment, and 110 of these responders entered the random-assignment portion of the study. In the first 16 weeks after randomization, patients who discontinued to placebo (Arm 3) showed greater rates of relapse than those who continued on risperidone (Arms 1 and 2) (hazard ratio=1.94, 95% confidence interval [CI]=1.09-3.45,  $P=0.022$ ), for a relapse rate of 60% (24/40) for placebo versus 32.9% (23/70) for risperidone ( $P=0.004$ ). During the second 16 weeks, relapse rates were again greater with discontinuation to placebo (Arm 2) compared with continuation risperidone (Arm 1) (hazard ratio=4.88, 95% CI=1.08-21.98,  $P=0.023$ ), for a relapse rate of 48.1% (13/27) for placebo versus 15.4% (2/13) for risperidone ( $P=0.017$ ). Postrandomization adverse events and deaths did not differ significantly, although comparisons were based on small numbers of patients, especially during the final 16 weeks. The results showed that among Alzheimer's disease patients with psychosis or agitation who maintained response to risperidone for 4-8 months, risperidone discontinuation was associated with an

increased risk of relapse ([Devanand et al. 2012](#)). The authors' clinical recommendation, which applies to the issue of antipsychotic withdrawal in nursing homes as per federal guidelines, is that if a patient has shown a clear response to antipsychotic treatment, that patient should be continued on treatment for several months (up to 8 months based on this study) as long as side effects are not prominent. In contrast, if a patient's symptoms do not clearly respond to antipsychotic treatment, it is advisable to withdraw the treatment in order to reduce the likelihood of persistent side effects or the development of future complications, including an increased risk of mortality.

## **Antipsychotic Effects on Cognition and Activities of Daily Living**

The anticholinergic activity of antipsychotics may further compromise the already damaged central cholinergic projections in Alzheimer's disease. The level of cognitive impairment may be increased by the use of antipsychotics with strong anticholinergic properties or by the addition of anticholinergic agents to treat drug-induced EPS. Therefore, if EPS develops following antipsychotic treatment in a patient with dementia, switching to an antipsychotic that is less likely to cause EPS is preferable to adding an anticholinergic medication to treat the EPS. At another level, the sedation produced by antipsychotics may worsen the degree of disorientation and cognitive impairment in Alzheimer's disease.

## **Antipsychotic Blood-Level Monitoring**

Few studies have examined the utility of monitoring antipsychotic blood levels in patients with dementia. In a

study that compared haloperidol 2–3 mg/day, haloperidol 0.5–0.75 mg/day, and placebo, plasma haloperidol levels were detectable in all patients at the 2–3 mg daily dosage, and blood levels showed stronger correlations with efficacy and EPS than did oral dosages ([Pelton et al. 2003](#)). In this series of predominantly drug-naïve Alzheimer's disease patients, therapeutic effects occurred at haloperidol blood levels that were invariably below the postulated therapeutic window of 5–15 ng/mL in schizophrenia ([Van Putten et al. 1992](#); [Volavka et al. 1992](#)). Also, EPS developed in some patients at these low blood levels, suggesting that the increased sensitivity to antipsychotics seen in dementia is not likely to be attributable to pharmacokinetic changes. A pharmacodynamic explanation (e.g., loss of dopamine receptors leading to greater sensitivity to even low oral dosages of antipsychotic medication) is more likely. In contrast to the associations observed with the typical antipsychotic haloperidol, clinically relevant associations between blood levels of atypical antipsychotics such as risperidone and either efficacy or side effects have not been demonstrated ([Jeste 2000](#)).

## **Treatment Monitoring of Target Behavioral Symptoms**

The heterogeneous nature of behavioral complications suggests that specific target symptoms should be identified before initiating antipsychotic treatment, and these target symptoms should be monitored serially during the course of treatment. A scale such as the NPI can also be used. In addition to neurological and other common antipsychotic side effects, cognition and activities of daily living need to be monitored, preferably with brief instruments such as the

MMSE. In patients who are being maintained on antipsychotics for extended periods, assessment for TD using the Abnormal Involuntary Movement Scale should be conducted at regular intervals.

## Antipsychotics in Other Neurodegenerative Disorders in the Elderly

The relative efficacy of antipsychotics in other subtypes of dementia (e.g., vascular dementia or mixed dementia, frontotemporal dementia) has not been studied extensively. Antipsychotic treatment trials that included patients with vascular, mixed, and other forms of dementia did not reveal any differences in treatment response among the diagnostic subtypes of dementia ([De Deyn et al. 1999](#); [Katz et al. 1999](#)). With the exceptions of diffuse Lewy body disease (DLBD) and Parkinson's disease, in which EPS are likely to worsen with antipsychotics, the recommendations for the use of antipsychotics in Alzheimer's disease generally apply to their use in other types of dementia.

DLBD is a subtype of dementia characterized by prominent EPS, fluctuating clinical course, hallucinations, and extreme sensitivity to the neurological side effects of antipsychotics ([McKeith 2006](#)). DLBD has features that overlap with those of Alzheimer's disease and Parkinson's disease, and the boundaries of DLBD as a diagnostic entity remain controversial. Sensitivity to typical antipsychotics is one of the defining criteria for DLBD ([McKeith 2006](#)), and atypical antipsychotics may be safer to use in these patients. A post hoc analysis of the olanzapine dosage

comparison study in Alzheimer's disease suggested that olanzapine was safe and effective for the subgroup of patients who met diagnostic criteria for DLBD ([Cummings et al. 2002](#)). Patients with Parkinson's disease can develop iatrogenic psychosis caused by the levodopa-carbidopa combination (Sinemet) or dopamine agonists. Lowering the dosage of the dopaminergic agent will often lead to remission of psychotic symptoms, but the price paid may be an unacceptable increase in parkinsonian symptoms ([Breier et al. 2002b](#)). In such cases, antipsychotics with a very low propensity to cause EPS can be considered. However, two double-blind, placebo-controlled trials did not find an advantage for olanzapine over placebo in these patients ([Breier et al. 2002b](#)). Clozapine may be of some value in patients with Parkinson's disease ([J.H. Friedman and Fernandez 2002](#)), but quetiapine may be the preferred antipsychotic in this disorder. Long-term quetiapine use is generally well tolerated in patients with Parkinson's disease or DLBD ([Fernandez et al. 2002](#)). Pimavanserin, a selective inverse agonist at the serotonin 5-HT<sub>2A</sub> receptor, has been shown to be efficacious in treating psychosis in Parkinson's disease ([Cummings et al. 2014](#)).

In patients with delirium, short-term administration of antipsychotics—particularly antipsychotic agents with low anticholinergic properties, such as haloperidol—is a standard treatment strategy ([Tune 2002](#)). Atypical antipsychotics are useful in the management of delirium, and olanzapine has been reported to be safe and efficacious for the treatment of symptoms of delirium in hospitalized patients ([Breitbart et al. 2002](#)).

# Antipsychotics in Late-Life Schizophrenia

The majority of elderly schizophrenic patients were first diagnosed as young adults, but a minority of patients are first diagnosed with schizophrenia later in life. The International Late-Onset Schizophrenia Group reached a consensus that the diagnoses of late-onset schizophrenia (onset after age 40 years) and very-late-onset schizophrenia (onset after age 60 years) have face validity and clinical utility ([Howard et al. 2000](#)). Although age at onset affects the clinical presentation to some extent ([Sable and Jeste 2002](#)), it does not appreciably influence the likelihood of response to antipsychotics or the occurrence of side effects ([Sable and Jeste 2002](#)).

## Studies in Elderly Patients With Schizophrenia

Tapering and stopping antipsychotic medications in schizophrenia is associated with a high risk of relapse ([Csernansky and Schuchart 2002](#)). This risk has made it difficult to conduct placebo-controlled trials in samples of elderly schizophrenic patients ([Sable and Jeste 2002](#)). In elderly schizophrenic patients, switching from typical antipsychotics to risperidone has been reported to be effective and well tolerated ([Barak et al. 2002](#)). Atypical antipsychotics appear to be at least as efficacious as and better tolerated than typical antipsychotics in the elderly, and a study of veterans suggested that adherence to atypical antipsychotics is slightly higher than adherence to typical antipsychotics ([Dolder et al. 2002](#)).

In a 4-month comparison trial of flexible-dose risperidone ( $n=175$ ) versus quetiapine ( $n=553$ ) in 728 mixed-age

patients with a variety of psychotic disorders, quetiapine was as effective as risperidone and was less likely to require adjustment of concomitant antiparkinsonian medication. However, quetiapine was associated with more sedation, dry mouth, and dizziness ([Mullen et al. 2001](#)). Quetiapine was evaluated in a sample of 151 elderly psychotic patients (mean age: 77 years), among whom 40% had schizophrenia, bipolar disorder, or psychotic depression; 50% had psychosis associated with Alzheimer's disease; and 10% had psychosis associated with Parkinson's disease. The median quetiapine dosage was 100 mg/day (range = 100–400 mg/day). Significant improvement was seen in the primary outcome measure of psychosis as measured by the BPRS ( $P<0.0001$ ) and Clinical Global Impression Scale ( $P<0.01$ ). The prominent side effects included somnolence in 32%, dizziness or postural hypotension in 13%, and EPS in 6% ([McManus et al. 1999](#)).

In 184 elderly patients (mean age: 76.1 years), 72% with Alzheimer's disease and 28% with other psychoses (mainly schizophrenia), open-label quetiapine was administered over 52 weeks. Quetiapine at a median dosage of 137.5 mg/day was effective, with 49% of the patients showing a 20% or greater decline in BPRS scores. The main side effects were sedation (31%), dizziness (17%), and postural hypotension (15%) ([Tariot et al. 2000](#)). EPS-related adverse events occurred in 13% of patients, but overall ratings on an EPS scale showed a small improvement from baseline, and new-onset TD did not develop in any patient over the 1-year period. Although limited by the lack of placebo control or comparison with another antipsychotic to establish efficacy, the relatively benign side-effect profile of quetiapine is noteworthy. The CATIE studies in patients with Alzheimer's disease suggested that quetiapine's lack of

efficacy compared with olanzapine and risperidone (quetiapine did not separate from placebo) should be an equally important consideration ([Schneider et al. 2006](#)).

In all age groups, it has been difficult to demonstrate that the atypical antipsychotics approved for use in the United States improve negative symptoms (e.g., anhedonia, apathy), even though this putative effect was one of the factors driving the development of these compounds. However, medications approved in Europe (e.g., amisulpride) have been shown to be efficacious in improving the negative symptoms of schizophrenia in controlled studies ([Möller 2001](#)).

## **Treatment and Dosing**

In elderly patients with schizophrenia, a thorough evaluation followed by treatment with low dosages of atypical antipsychotics is the optimal strategy. When appropriate, antipsychotic treatment may need to be combined with psychosocial intervention ([Sable and Jeste 2002](#)).

The dosages of typical antipsychotics used in elderly patients with schizophrenia need to be lower than the dosages used in young adults ([Jeste 2000](#)). Abrupt withdrawal of atypical antipsychotics, particularly quetiapine, has not been shown to cause major adverse effects, but nonetheless, gradual withdrawal over a few days is advisable for all antipsychotics ([Cutler et al. 2002](#)). Although atypical antipsychotics can be safely combined with cholinesterase inhibitors in schizophrenia, a study in patients receiving risperidone found no cognitive benefit from adding donepezil compared with adding placebo ([J.I. Friedman et al. 2002](#)).

# Antipsychotics in Other Psychotic Disorders in the Elderly

Late-onset delusional disorder is uncommon. As is the case in young adults, delusional disorder in elderly individuals is difficult to treat, and the delusions often do not remit even with adequate antipsychotic treatment. The diagnosis of paraphrenia overlaps considerably with current nomenclature for late-onset schizophrenia, and atypical antipsychotics are the treatment of choice for this disorder ([Howard et al. 2000](#)).

Psychotic depression is an uncommon but clinically important diagnosis in the elderly. Based on studies in mixed-age samples, antipsychotics combined with antidepressants are the pharmacological treatment of choice in psychotic depression, but electroconvulsive therapy (ECT) is still considered the most effective treatment for this disorder ([Mulsant et al. 2001b](#); [Sackeim et al. 1995](#); [Spiker et al. 1985](#)). Expert consensus guidelines suggest that antipsychotic medication should be continued for 6 months following treatment response in psychotic depression ([Alexopoulos et al. 2001](#)). A double-blind trial of combination pharmacotherapy for psychotic depression showed that treatment with olanzapine plus sertraline was superior to treatment with olanzapine plus placebo in both older ( $\geq 60$  years) and younger adult patients, a finding that highlights the importance of combination antipsychotic and antidepressant treatment ([Meyers et al. 2009](#)).

Antipsychotics are used widely in the treatment of the manic phase of bipolar disorder across the life span ([Levine et al. 2000](#)). In bipolar disorder, there is ample evidence for

the efficacy of typical and atypical antipsychotics, both individually and in combination with mood stabilizers ([Sachs et al. 2002](#); [Tohen et al. 2002](#)). However, there is a surprising lack of data on the use of antipsychotics in geriatric patients with bipolar disorder. Lithium's toxicity, particularly in the neurological domain, is problematic in the elderly ([McDonald 2000](#)). Hence, anticonvulsants and atypical antipsychotics are frequently used to treat mania in elderly patients. However, in the absence of controlled data, the optimal choice of antipsychotic and the optimal dosage to use in these patients are open questions that need to be answered in future research.

Although obsessive-compulsive disorder is not considered a psychotic illness, there is evidence that atypical antipsychotics are useful adjunctive medications in adults with this disorder ([Denys et al. 2002](#)). However, comparable data are lacking in geriatric patients.

---

## Conclusion

---

Clearly, antipsychotic medications, particularly atypical antipsychotics, have an important role to play in the treatment of psychosis and behavioral dyscontrol in Alzheimer's disease, other types of dementia, and other neurodegenerative conditions. Antipsychotics remain the first-line treatment for schizophrenia and other psychotic disorders across the life span. When antipsychotic medications are used in elderly patients, monitoring of target symptoms, somatic side effects, potential drug interactions, cognition, and activities of daily living is necessary.

## CHAPTER 57

# **Psychopharmacology During Pregnancy and Lactation**

Shona L. Ray-Griffith, M.D.

D. Jeffrey Newport, M.D.

Zachary N. Stowe, M.D.

The management of mental illness during pregnancy and lactation is a complicated clinical challenge encompassing two concomitant medical conditions (i.e., pregnancy and a psychiatric disorder) that requires consideration of the welfare of at least two patients (i.e., mother and child). Various nonpharmacological treatment options for maternal mental illnesses during the antepartum and postpartum periods are beyond the scope of this chapter. Viable treatment options must be available, accessible, affordable, and effective for the illness, and in many cases, this may involve pharmacotherapy.

Unfortunately, definitive treatment guidelines for perinatal psychotropic medications remain unavailable. In the two decades since the initial iteration of this chapter, there has been an enormous expansion in the reproductive safety literature focusing on psychotropic medications.

In this chapter, we posit that minimizing infant exposure to the purported risks of both maternal mental illness and psychotropic medications is the preeminent clinical objective. Investigations and reviews focusing on reproductive safety of psychotropic medications typically provide only cursory information about the effect of illness, rely on maternal self-report to address concomitant fetal exposures, and use extensive statistical interrogation that may not have meaningful clinical import.

Space limitations preclude a comprehensive review of each class of psychotropic medications; rather, we review the available data with an emphasis on providing the clinician with the requisite components to interpret and apply medication reproductive safety data in the clinical decision. Also included are data regarding pharmacokinetic alterations during pregnancy and lactation and the potential clinical relevance of these data for psychotropic dosage management. The chapter concludes with a series of potential modifications of previously suggested treatment guidelines to optimize clinical decisions and a list of resources.

---

## **Minimizing Exposure of Offspring: Primary Therapeutic Objective**

---

The clinical management of any medical condition during pregnancy and lactation must consider the reproductive safety of available therapies, the likelihood of illness recurrence without continued treatment, and the potential effect of untreated maternal illness. Minor ailments, such as headaches and nausea, are routinely treated during pregnancy with medications that often have limited reproductive safety data. Recent data indicate that 90% of pregnant women take one medication and that more than 50% take four or more medications ([Ayad and Costantine 2015](#); [Mitchell et al. 2011](#)), confounding the ability to isolate the effect of an individual medication. Women with mental illness are frequently encouraged to discontinue psychotropic medication during pregnancy, and pregnancy is associated with high rates of both antidepressant discontinuation ([Petersen et al. 2011](#)) and nonadherence to prescribed psychiatric medications ([Lupattelli et al. 2015](#)). The desire to avoid offspring exposure to psychotropic medication is laudable; however, recommendations to discontinue medication are often made with limited knowledge of the potential risk of recurrent illness and of the effect of maternal illness on obstetrical and child outcomes.

An assessment of the risks of offspring exposure to maternal psychiatric illness must consider both the likelihood that an episode of illness will occur and the evidence that the illness may be harmful to the child. The clinician can estimate a patient's likelihood of experiencing illness recurrence or exacerbation by carefully synthesizing prevalence data from epidemiological studies with evidence from the patient's own history. Patients with frequent episodes of psychiatric illness, a declining course, or a

history of perinatal illness are more likely to become ill in the current pregnancy or the postpartum period.

Investigations of the incidence and course of maternal mental illness have found no evidence that mental illness lies quiescent during pregnancy and considerable evidence that the postpartum period entails heightened vulnerability. The incidence of depression during the perinatal period is comparable to that in other populations ([Buesching et al. 1986](#); [Cutrona 1983](#); [Kumar and Robson 1984](#); [Manly et al. 1982](#); [O'Hara et al. 1982](#); [Watson et al. 1984](#)). Two large studies, collectively comprising 122,400 women, found a 14%–20% incidence of prenatal major depressive disorder (MDD) ([Marcus et al. 2003](#); [Oberlander et al. 2006](#)). In fact, 11% of women presenting for evaluation of postpartum depression report symptom onset before delivery ([Stowe et al. 2005](#)). Discontinuation of treatment during pregnancy in women with histories of MDD or bipolar disorder increases the risk of episodes during pregnancy ([Cohen et al. 2006](#); [Newport et al. 2008c](#); [Viguera et al. 2007b](#)). However, one group failed to identify an increase in depression with antidepressant discontinuation ([Yonkers et al. 2011](#)).

*Psychotic disorders* also may worsen during pregnancy ([Glaze et al. 1991](#); [McNeil et al. 1984a, 1984b](#)). The course of *obsessive-compulsive disorder* (OCD) appears to be variable during pregnancy, with 14%–33% of patients experiencing exacerbation ([Guglielmi et al. 2014](#); [Jenike et al. 1990](#); [Williams and Koran 1997](#)). Women with OCD who continued pharmacotherapy throughout the perinatal period did not have a significant change in symptoms ([House et al. 2016](#)). *Panic disorder* during gestation is also variable, with 19% of patients experiencing more frequent panic attacks and 30% having less frequent attacks ([Hertzberg and Wahlbeck 1999](#); [Wisner et al. 1996a](#)).

Finally, obstetrical trauma and pregnancy loss can precipitate *posttraumatic stress disorder* (PTSD) (Allen 1998; [Engelhard et al. 2001](#); [Fones 1996](#)), with PTSD symptoms following stillbirth persisting into the next pregnancy ([Turton et al. 2001](#)).

Postpartum mental illness has been documented for millennia and is substantiated by modern research. Early studies reported that psychiatric hospitalization rates increased during the first postpartum month ([Kendler et al. 1993](#)) and noted that up to 12.5% of all psychiatric admissions for women occurred during the first postpartum year ([Duffy 1983](#)). Postpartum depression affects 10%–22% of adult mothers and up to 26% of adolescent mothers ([Stowe and Nemeroff 1995](#); [Troutman and Cutrona 1990](#)). Women with bipolar disorder also face considerable postpartum risks ([Kendell et al. 1987](#); [Targum et al. 1979](#)). Postpartum OCD, often manifested by violence and contamination obsessions, may affect 9%–16% of new mothers ([Miller et al. 2013](#); [Zambaldi et al. 2009](#)), with one-third experiencing new-onset OCD symptoms during the postpartum period ([Miller et al. 2013](#)). Nearly one-half of women with preexisting OCD report an exacerbation of symptoms during the postnatal period ([Guglielmi et al. 2014](#)). Thankfully, postpartum psychosis, the most severe postpartum syndrome, is a rare condition; however, its prevalence is at least 100-fold higher among women with bipolar disorder than among those with other affective or psychotic disorders ([Brockington et al. 1982](#); [Kendell et al. 1987](#)).

---

# Effect of Maternal Psychiatric Disorders

---

Not only the likelihood but also the potential effect of maternal mental illness on maternal and child well-being must be considered. Most studies focusing on obstetrical and developmental outcomes have focused on the effect of maternal depression, anxiety, and stress. Often these terms are used interchangeably, with most previous investigations focusing on maternal symptoms rather than diagnosis. Given the high rate of comorbidity of mood and anxiety disorders in women, the distinction between maternal depression and maternal anxiety may not have clinical import. The effect of maternal unipolar versus bipolar depression during gestation remains unexplored. Maternal depression during pregnancy has been associated with slower fetal growth ([Hedegaard et al. 1996](#); [Schell 1981](#); [Uguz et al. 2013](#)); increased risk of preterm delivery and other obstetrical complications ([Korebrits et al. 1998](#); [Liu et al. 2016](#); [Oberlander et al. 2006](#); [Orr and Miller 1995](#); [Perkin et al. 1993](#); [Steer et al. 1992](#); [Uguz et al. 2013](#); [Venkatesh et al. 2016](#)); and long-standing cognitive, behavioral, and emotional changes in the offspring ([Luoma et al. 2001, 2004](#); [Meijer 1985](#); [Nulman et al. 2002](#); [O'Connor et al. 2003](#); [Søndergaard et al. 2003](#); [Stott 1973](#)). Similarly, prenatal panic disorder is associated with higher rates of preterm birth and low birth weight ([Uguz et al. 2013](#)), and maternal anxiety is associated with higher rates of attentional problems ([Van den Bergh and Marcoen 2004](#)). Depressed pregnant women are less compliant with prenatal vitamins and obstetrical care; receive poorer nutrition; and have greater use of prescription opiates,

hypnotics, alcohol, tobacco, and illicit substances ([Newport et al. 2012](#); [Zuckerman et al. 1989](#)). Finally, depressed pregnant women, and those with PTSD, often experience suicidal thoughts ([Newport et al. 2007b](#); [Smith et al. 2006](#)) and may engage in suicidal behavior.

Postpartum depression also carries deleterious consequences for infant development. As early as 3 months, infants of depressed mothers show less facial expression, less head orientation, less crying, and more fussiness compared with infants of nondepressed mothers ([Martinez et al. 1996](#)). As they age, the children of depressed mothers show ineffective emotional regulation ([Downey and Coyne 1990](#)), delayed motor development ([Galler et al. 2000](#)), poor interpersonal skills ([Jameson et al. 1997](#)), lower self-esteem ([Downey and Coyne 1990](#)), increased fear and anxiety ([Lyons-Ruth et al. 2000](#)), more aggression ([Jameson et al. 1997](#)), and more insecure and disorganized attachment behaviors ([Martins and Gaffan 2000](#)). Children of depressed mothers are ultimately more likely to experience emotional instability, to have behavior problems and suicidal behavior, and to require psychiatric treatment ([Lyons-Ruth et al. 2000](#); [Weissman et al. 1984](#)).

Antepartum exacerbation of schizophrenia and other psychotic illnesses also warrants concern. Women with schizophrenia have a higher prevalence of substance abuse during pregnancy ([Miller and Finnerty 1996](#); [Taylor et al. 2015](#)) and may have bizarre ideas about contraception, pregnancy, and child rearing that complicate their perinatal course ([McEvoy et al. 1983](#); [Riordan et al. 1999](#)). Maternal schizophrenia has been associated with elevated rates of obstetrical complications ([Bennedsen et al. 2001](#); [Miller and Finnerty 1996](#)) and fetal and neonatal death ([Rieder et al. 1975](#)).

The clinical data regarding the obstetrical and developmental consequences of maternal mental illness are supported by an extensive line of laboratory animal research. Preclinical studies across a variety of species indicate that stress during pregnancy and the early postpartum period adversely affects offspring growth, learning ability, and postnatal development, producing a range of biobehavioral aberrations that may persist into adulthood (for a review, see [Newport et al. 2002](#)).

---

## **Risks of Antepartum and Postpartum Exposure to Psychotropic Medication**

---

Clinical decisions during pregnancy and the postpartum period must consider the risks of fetal and neonatal medication exposure. These risks may be broadly classified as acute or developmental adverse effects ([Table 57-1](#)). *Acute effects* are typically immediately evident and are not dependent on the developmental window of exposure. Examples include drug toxicity, drug withdrawal, and drug-drug interactions. *Developmental effects* are, by definition, dependent on the developmental window of exposure and are often not evident until later. These effects include somatic teratogenesis (i.e., major and minor malformations) and neurobehavioral teratogenesis (i.e., alterations in brain development that affect the child's subsequent behavior, cognitive abilities, and emotional regulation). The window of vulnerability to somatic teratogenesis is limited to the embryonic phase of development, but because central

nervous system (CNS) development continues long after delivery, the fetus and breast-feeding infant are equally vulnerable to the theoretical risks of neurobehavioral teratogenesis.

**TABLE 57-1. Potential risks of medication exposure**

	<b>Acute</b>	<b>Developmental</b>
Pregnancy	Neonatal toxicity	Somatic teratogenesis
	Neonatal withdrawal	Neurobehavioral teratogenesis
	Drug-drug interactions	
Lactation	Infant toxicity	Neurobehavioral teratogenesis
	Drug-drug interactions	

A decision to use psychotropic medication during pregnancy and/or lactation will carry complicated clinical, ethical, and potentially legal consequences. Although a rapidly expanding base of reproductive safety data has begun to address many of these concerns, review of the current literature reveals numerous methodological problems. The most glaring deficiencies are a frequent lack of appropriate control groups and an overreliance on retrospective data collection—deficiencies shown to introduce systematic biases that potentially lead to overestimation of the effect of psychotropic exposure ([Newport et al. 2008a](#)). In particular, most studies report outcomes of “depressed-treated women compared with

nondepressed-untreated women,” eliminating any opportunity to disentangle treatment and illness effects on outcomes (McDonagh et al. 2014). Despite these limitations, ethical considerations preclude implementation of randomized controlled trials to evaluate psychotropic efficacy and safety during pregnancy and lactation. Therefore, the reproductive safety database for psychotropic medications is composed of a diverse conglomeration of case reports, case series by pharmaceutical companies and academic centers, birth registries, retrospective surveys, reports from teratology or poison control centers, clinical and preclinical pharmacokinetic investigations, review articles summarizing data from these sources, and the U.S. Food and Drug Administration (FDA) medication safety rating systems (Table 57-2).

**TABLE 57-2. U.S. Food and Drug Administration use-in-pregnancy ratings (prior to 2015)**

Category Interpretation	
A	<b>Controlled studies show no risk:</b> Adequate, well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
B	<b>No evidence of risk in humans:</b> Either animal findings show risk, but human findings do not; or, if no adequate human studies have been done, animal findings are negative.

Source. Physicians’ Desk Reference 2007.

## Category Interpretation

---

- C      **Risk cannot be ruled out:** Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
  - D      **Positive evidence of risk:** Investigational or postmarketing data show risk to the fetus. Nevertheless, potential benefits may outweigh risks.
  - X      **Contraindicated in pregnancy:** Studies in animals or humans, or investigational or postmarketing reports, have shown fetal risk that clearly outweighs any possible benefit to the patient.
- 

*Source.* [Physicians' Desk Reference 2007](#).

In addition to the available reproductive safety data, the patient's clinical history is important in treatment selection. If the rationale for psychotropic therapy during pregnancy is to protect the mother and the child from the harmful sequelae of maternal mental illness, then a history of treatment response or nonresponse is critical. Regardless of the favorability of its reproductive safety profile, a medication that has been ineffective for or poorly tolerated by a particular patient is of little value during the reproductive period.

---

# FDA Reproductive Safety Ratings

---

On June 30, 2015, the FDA's new Pregnancy and Lactation Labeling Rule became effective, with a plan for staggered implementation over the following 3–5 years. The new labeling rule eliminates the pregnancy letter category previously used (see [Table 57-2](#)) and provides the following information for the use of medications in pregnancy and delivery when available: 1) pregnancy exposure registry, 2) narrative risk summary, 3) clinical considerations, and 4) data description of supporting evidence. Specifically, the clinical considerations are as follows: disease-associated maternal and embryo/fetal risk, dosage adjustment, maternal adverse reactions, fetal/neonatal adverse reactions, and labor or delivery. Two new sections also summarize evidence for lactation and evidence for males and females of reproductive potential. The labeling will be updated as evidence emerges but is required only for medications receiving FDA approval after June 30, 2001. Medications approved prior to this date are strongly encouraged to comply with the new recommendations but are not required to do so.

The result of these changes is two unintegrated systems for reproductive safety ratings that present a challenge for clinicians. Similarly, the rate of accrual for reproductive safety information in humans is variable and all obtained postmarketing. The new safety ratings will arguably have greater clinical import, because the older system often provided more favorable ratings to newer medications with very limited information and was often overvalued in clinical decisions. For example, a clinician may be tempted

to use buspirone (Category B) over clonazepam (Category D) for panic disorder despite the very limited information underlying buspirone's preferable pregnancy rating and its lack of efficacy for panic disorder. Similarly, lurasidone (Category B) may be used in lieu of lithium (Category D) for bipolar depression despite the virtual absence of human data on lurasidone's safety during gestation and the lack of published clinical experience in the antepartum and postpartum periods.

---

## Dosage Management: Perinatal Pharmacokinetics

---

Prescribing the *minimal effective dosage* is especially important during pregnancy and lactation. On learning that a patient is pregnant, clinicians and patients often instinctively lower psychotropic dosages in an effort to reduce fetal exposure, but indiscriminate dosage reduction may increase the vulnerability to relapse. If the therapeutic objective is to eliminate the child's exposure to maternal illness while minimizing the child's psychotropic exposure, then dosage management must be informed by an understanding of the factors governing the alterations in drug disposition across gestation, the placental passage, and excretion into breast milk.

Dosage adjustments may be required to maintain medication efficacy during pregnancy. For example, it may be necessary to increase the dosage of tricyclic antidepressants (TCAs) to approximately 1.6 times the preconception dosage to maintain therapeutic concentrations in late pregnancy ([Altshuler et al. 1996](#);

[Wisner et al. 1993](#)). Small studies examining selective serotonin reuptake inhibitors (SSRIs) have reported clearance changes over the course of pregnancy and the necessity for dosage adjustments in response to increased maternal symptoms ([Freeman et al. 2008](#); [Hostetter et al. 2000](#); [Sit et al. 2008](#)). However, the pattern of dosage adjustment during gestation is not uniform for all medications. For example, among anticonvulsant and mood-stabilizing medications, serum concentrations of lamotrigine ([Ohman et al. 2000](#); [Pennell et al. 2004](#); [Polepally et al. 2014](#); [Tran et al. 2002](#)) and valproate ([Otani 1985](#); [Philbert et al. 1985](#)) decline steadily across gestation, whereas carbamazepine concentrations ([Bardy et al. 1982b](#); [Battino et al. 1982](#); [Bologa et al. 1991](#); [Dam et al. 1979](#); [Lander et al. 1981](#); [Omtzigt et al. 1993](#); [Otani 1985](#); [Tomson et al. 1994](#); [Yerby et al. 1985](#)) undergo smaller changes that are primarily evident only in late pregnancy. These alterations in drug concentrations and dosing requirements likely result from effects of the physiological changes of pregnancy on the pharmacokinetics ([Boobis and Lewis 1983](#); [Frederiksen 2001](#); Little 1999; [Wyska and Jusko 2001](#)) and possibly the pharmacodynamics ([Wyska and Jusko 2001](#)) of psychotropic medications. Ultimately, an improved understanding of the factors governing perinatal pharmacokinetic and pharmacodynamic alterations may enable the development of personalized dosing strategies during gestation.

The level of fetal psychotropic exposure is another key consideration. All psychotropics studied to date cross the human placenta; yet there are significant differences in placental passage rates. Bidirectional placental transfer is mediated primarily by simple diffusion, and determinants of the transplacental diffusion rate include molecular weight,

lipid solubility, degree of ionization, and protein-binding affinity ([Audus 1999](#); W.M. [Moore et al. 1966](#); [Pacifici and Nottoli 1995](#)). In addition, placental P-glycoprotein (P-gp), which actively transports substrates from the fetal to the maternal circulation, is likely a key determinant of fetal psychotropic exposure. Consequently, medications with greater affinity for P-gp should be associated with lower fetal-to-maternal medication ratios, which, in fact, has been confirmed in an investigation of antipsychotic placental passage ([Newport et al. 2007a](#)). Furthermore, clarification of the factors governing placental passage may ultimately contribute to the development of psychotropic agents with minimal rates of placental transfer ([Wang et al. 2007](#)).

Fetal plasma concentrations are not, however, the ultimate measure of functional psychotropic exposure and may even underestimate the more critical measure of fetal brain concentration. Certain physiological attributes of the human fetus, including high cardiac output, increased blood-brain barrier permeability, low plasma protein concentrations and plasma protein binding affinities, and low hepatic enzyme activity ([Bertossi et al. 1999](#); [Morgan 1997](#); [Oesterheld 1998](#)), may produce higher-than-anticipated fetal CNS concentrations of psychotropic medications than might be anticipated from circulating levels. Preclinical investigations from our group have found that transplacental passage of psychotropic drugs results in high levels in fetal CNS tissues and significant binding at neurotransmitter receptor and transporter sites ([Capello et al. 2011](#)).

Similar considerations apply when endeavoring to minimize the psychotropic exposure of nursing infants. Because the neonate has relatively low hepatic enzyme activity ([Warner 1986](#)) and low glomerular filtration and

tubular secretion rates ([Welch and Findlay 1981](#)), psychotropic exposure may be higher than anticipated for breast-fed infants. A model to predict rates of breast-milk excretion from characteristics of the molecular structure of candidate medications has been proposed ([Agatonovic-Kustrin et al. 2002](#)). Such models may allow clinicians to estimate a nursing infant's exposure without subjecting the infant to invasive procedures.

---

## Antidepressants

---

The use of antidepressant medications in pregnancy has been extensively reviewed ([McDonagh et al. 2014](#); [Yonkers et al. 2014](#)), and multiple meta-analyses have found no association between antidepressant use in pregnancy and congenital malformations and/or major malformations ([Einarson and Einarson 2005](#); [Grigoriadis et al. 2013](#)). We include an overview of the individual categories of antidepressants in this section.

## Selective Serotonin Reuptake Inhibitors

Reproductive safety data on the SSRIs have rapidly accrued over the past two decades. A recent meta-analysis investigating SSRIs found no overall association with birth defects ([Reefhuis et al. 2015](#)). Despite overall reassuring data, some concerns with specific SSRIs have emerged. [Reefhuis et al. \(2015\)](#) found an increased risk of anencephaly, atrial septal defects, right ventricular outflow

tract obstruction, gastroschisis, and omphalocele with paroxetine and an increased risk of right ventricular outflow tract obstruction defects and craniosynostosis with fluoxetine. Analysis of a managed care database identified a higher odds ratio (OR) for cardiovascular malformations with exposure to paroxetine compared with other antidepressants ([GlaxoSmithKline 2005](#)). Three large case-control studies of SSRI exposures ([Alwan et al. 2007](#); [Bérard et al. 2007](#); [Louik et al. 2007](#)) reported largely reassuring results, although with some concerns. The first ([Alwan et al. 2007](#)) reported small increases in the risk of three uncommon malformations—anencephaly (OR=2.4), craniosynostosis (OR=2.5), and omphalocele (OR=2.8) associated with use of fluoxetine, sertraline, or paroxetine. The second study ([Louik et al. 2007](#)) reported an increased risk of omphalocele (OR=5.7) and septal defects (OR=2.0) with sertraline exposure and of right ventricular outflow tract obstruction defects (OR=3.3) with paroxetine exposure. The third study ([Bérard et al. 2007](#)) found no evidence of increased risk of cardiovascular or other malformations with SSRI use, unless women were taking paroxetine at daily dosages of 25 mg or greater, in which case their infants were at an increased risk of cardiovascular (OR=3.1) and overall malformations (OR=2.2). In the Medicaid Analytic eXtract (MAX) database, [Huybrechts et al. \(2014a\)](#) found an overall adjusted risk of 1.06 (95% confidence interval [CI]=0.93–1.22) for any cardiac defect with use of an SSRI in the first trimester; a risk of 1.07 (95% CI=0.59–1.93) for a right ventricular outflow tract obstruction with use of paroxetine; and a risk of 1.04 (95% CI=0.76–4.41) for a ventricular septal defect with use of sertraline.

A handful of studies have systematically assessed child development after prenatal exposure to antidepressants. Two studies ([Nulman et al. 1997a, 2002](#)) assessed children (ages 15–86 months) who had been prenatally exposed to fluoxetine ( $n=90$ ) or TCAs ( $n=126$ ), collectively comparing them with nonexposed children ( $n=120$ ). No differences were observed with respect to global cognitive, psychomotor, or language development. The same research group compared children exposed to SSRIs in utero with children of mothers without depression or SSRI use and found no difference in IQ or behavior ([Nulman et al. 2012](#)). A similar study that compared children (ages 6–40 months) with prenatal SSRI exposure ( $n=31$ ) and children without antidepressant exposure ( $n=13$ ) observed no differences in global cognition but reported lower psychomotor scores for the SSRI-exposed children ([Casper et al. 2003](#)).

Unfortunately, limitations of these studies render their implications speculative at best. Children were not age-matched in any of these studies, and the predictive validity of measured indices across child developmental stages has not been established ([Black and Matula 2000](#)). In addition, the [Casper et al. \(2003\)](#) study was confounded by the fact that 29% of the participants were enrolled after delivery, which could have resulted in an overrepresentation of children with developmental abnormalities.

A study of 69 (46 SSRI-exposed; 23 nonexposed) children that eliminated the age confound by examining the children at two fixed time points—ages 2 months and 8 months—reported no differences between the exposed and the nonexposed children in cognitive or motor development ([Oberlander et al. 2004](#)). Finally, an assessment of 4-year-old children found no evidence that prenatal SSRI exposure affected externalizing or attentional behaviors ([Oberlander](#)

et al. 2007). It is noteworthy that several of these developmental studies involved a significant overlap in the cohort of children, thereby limiting further the cumulative sample size of extant follow-up studies.

Multiple studies have examined the association between maternal antidepressant use and autism spectrum disorders in offspring. The results were mixed, with four studies finding an association between antidepressant exposure and autism (Boukhris et al. 2016; Croen et al. 2011; El Marroun et al. 2014; Gidaya et al. 2014) and six finding no such association (Castro et al. 2016; Clements et al. 2015; Harrington et al. 2014; Hviid et al. 2013; Rai et al. 2013; Sørensen et al. 2013). In addition, close inspection reveals evidence of probable detection bias in at least some of these studies, with nonminority children of well-educated mothers overrepresented in the autism case subjects (Croen et al. 2011). These discordant and arguably flawed data preclude definitive conclusions regarding any autism risk attributable to prenatal antidepressant exposure.

Data regarding the effect of prenatal antidepressant exposure on rates of miscarriage, preterm delivery, and low birth weight are decidedly mixed. Some investigators have reported an association between antidepressant exposure and such outcomes (Chambers et al. 1996; Chun-Fai-Chan et al. 2005; Oberlander et al. 2006; Pastuszak et al. 1993; Ross et al. 2013; Simon et al. 2002), whereas others have not (Einarson et al. 2001, 2003; Kulin et al. 1998; Sivojelezova et al. 2005; Venkatesh et al. 2016). Multiple recent meta-analyses found an association between prenatal antidepressant exposure and preterm delivery (Huang et al. 2014; Huybrechts et al. 2014b; Ross et al. 2013) and low birth weight (Huang et al. 2014; Ross et al. 2013). Interpretation is complicated by other reports that

link prenatal maternal stress and/or depression with prematurity and low birth weight ([Orr et al. 2002](#); [Steer et al. 1992](#)). As a result, no definitive conclusions can be drawn as to whether antidepressant use during gestation conveys an adverse effect on fetal growth or the timing of parturition.

Finally, concerns have been expressed regarding neonatal SSRI syndromes, typically manifested by transient symptoms including respiratory difficulty and tremulousness ([Moses-Kolko et al. 2005](#)). Most controlled prospective studies suggest that SSRI exposure is associated with poor neonatal adaptation ([Chambers et al. 1996](#); [Costei et al. 2002](#); [Källén 2004](#); [Laine et al. 2003](#); [Oberlander et al. 2004, 2006](#); [Sivojelezova et al. 2005](#); [Zeskind and Stephens 2004](#)), although one study found no such association ([Maschi et al. 2008](#)). Closer scrutiny of these reports identified a cadre of methodological shortcomings. Limited effort was made to mask those evaluating the neonates as to exposure status, only one study ([Oberlander et al. 2006](#)) controlled for the effect of maternal mental illness, and key confounding factors such as gestational age at delivery and maternal use of other medications and/or habit-forming substances were either ignored altogether or controlled only in a rudimentary manner.

A case-control study comparing the exposures of neonates who “required observation” with those of “healthy” neonates ([Misri et al. 2004](#)) underscores the importance of controlling for confounding factors. In this study of antidepressant-exposed neonates ( $n=46$ ) born to mothers with MDD, the mothers of infants who required observation had more severe symptoms of depression and anxiety, were more likely to have a comorbid anxiety

disorder, and were exposed to higher dosages of clonazepam.

Debate has also focused on a more serious neonatal concern—a possible connection between late-pregnancy SSRI exposure and persistent pulmonary hypertension of the neonate (PPHN). A case-control study ([Chambers et al. 2006](#)) of 1,213 neonates (377 with PPHN) reported data supporting an association between SSRI exposure and PPHN (OR=6.1). However, a similar study of 1,104 SSRI-exposed neonates and 1,104 matched control subjects found no association ([Andrade et al. 2009](#)). A case-control study ([Källén and Olausson 2008](#)) of more than 831,000 neonates (of whom 506 were diagnosed with PPHN) from the Swedish Medical Birth Register observed a more modest association (OR=2.9). The overall rate of PPHN in this population-wide study was approximately 1 in 2,000, and the rate of PPHN with SSRI exposure was approximately 1 in 600. In the largest study to date, involving more than 3 million women, the adjusted odds of PPHN, after controlling for depression, was 1.10 (95% CI=0.77-1.35) for SSRI use and 1.14 (95% CI=0.74-1.74) for non-SSRI antidepressant use ([Huybrechts et al. 2015](#)). Finally, a study concluded that PPHN was associated not with SSRI exposure but rather with cesarean delivery prior to onset of labor ([Wilson et al. 2011](#)), underscoring the importance of controlling for all potential confounding factors. Overall, the SSRI-PPHN data are mixed, with a very low absolute rate of PPHN.

Pharmacokinetic data regarding the placental passage of SSRI antidepressants remain limited. However, existing studies have found that mean fetal-to-maternal ratios for numerous SSRIs and their active metabolites are uniformly

less than 1.0, although considerable differences exist among agents ([Hendrick et al. 2003](#); [Rampono et al. 2009](#)).

Published reports pertaining to SSRIs and lactation now encompass the largest data set for medications during breast feeding, including infant serum measures, breast milk concentrations, and pharmacokinetic studies of excretion. There are now published investigations for all of the SSRIs, including sertraline ([Altshuler et al. 1995](#); [Birnbaum et al. 1999](#); [Dodd et al. 2000](#); [Epperson et al. 1997, 2001](#); [Hendrick et al. 2001a](#); [Kristensen et al. 1998](#); [Mammen et al. 1997](#); [Stowe et al. 1997, 2003](#); [Wisner et al. 1998](#)), fluoxetine ([Birnbaum et al. 1999](#); [Burch and Wells 1992](#); [Goldstein et al. 1997](#); [Hendrick et al. 2001b](#); [Kristensen et al. 1999](#); [Lester et al. 1993](#); [Suri et al. 2002](#); [Taddio et al. 1996](#); [Yoshida et al. 1998a](#)), paroxetine ([Birnbaum et al. 1999](#); [Hendrick et al. 2001a](#); [Ohman et al. 1999](#); [Spigset et al. 1996](#); [Stowe et al. 2000](#)), escitalopram ([Rampono et al. 2006](#)), fluvoxamine ([Hendrick et al. 2001a](#); [Piontek et al. 2001](#); [Wright et al. 1991](#)), and citalopram ([Heikkinen et al. 2002](#); [Jensen et al. 1997](#); [Schmidt et al. 2000](#); [Spigset et al. 1997](#)). Although infant follow-up data are limited, only a few isolated cases of adverse effects have been reported. Long-term neurobehavioral studies of infants exposed to SSRI antidepressants during lactation warrant continued examination. The pharmacokinetic profiles of breast milk excretion, including delineation of distribution gradients and time gradients, are best defined for sertraline ([Stowe et al. 1997, 2003](#)), paroxetine ([Stowe et al. 2000](#)), and fluoxetine ([Suri et al. 2002](#)). These studies indicate that quantitative infant SSRI exposure during lactation is considerably lower than transplacental exposure.

## Other Antidepressants

Reproductive safety data are more limited for other classes of antidepressants, including bupropion, desvenlafaxine, duloxetine, mirtazapine, nefazodone, trazodone, venlafaxine, vilazodone, and vortioxetine. Prospective reports of first-trimester use of these agents have included 2,550 bupropion exposures producing 56 (2.2%) children with major malformations ([Boshier et al. 2003](#); [Briggs et al. 2005](#); [Chun-Fai-Chan et al. 2005](#); [Cole et al. 2007](#); [GlaxoSmithKline 2005](#)), 862 venlafaxine exposures with 91 (10.6%) major malformations ([Einarson et al. 2001](#); [GlaxoSmithKline 2005](#); [Polen et al. 2013](#)), 404 trazodone exposures with 10 (2.5%) major malformations ([Briggs et al. 2005](#); [GlaxoSmithKline 2005](#); [McElhatton et al. 1996](#)), 140 nefazodone exposures with 2 (1.4%) major malformations ([GlaxoSmithKline 2005](#)), 508 mirtazapine exposures with 14 (2.8%) major malformations ([Djulus et al. 2006](#); [GlaxoSmithKline 2005](#); [Smit et al. 2015](#); [Winterfeld et al. 2015](#)), and a combined report of 121 nefazodone or trazodone exposures with 2 (1.7%) major malformations ([Einarson et al. 2003](#)). For duloxetine, there have been 165 exposures with 3 (1.8%) major malformations ([Einarson et al. 2012](#)). The only reported case of vilazodone use in pregnancy resulted in a full-term, healthy neonate ([Morrison 2014](#)). No published data are yet available for prenatal vortioxetine exposure.

A single study that followed an infant until 9 months after in utero exposure to duloxetine reported normal infant cognitive, language, motor, and psychomotor development ([Bellantuono et al. 2013](#)). Likewise, children exposed to venlafaxine in utero showed no differences in IQ or

behavior compared with children of nondepressed mothers (Nulman et al. 2012).

A recent study found that prenatal exposure to serotonin-norepinephrine reuptake inhibitor antidepressants after the 20th week of gestation was associated with an increased risk of hypertensive disorders of pregnancy (OR=2.57; 95% CI=1.34-4.93), with an even higher (sixfold) increase among those receiving venlafaxine at dosages exceeding 187.5 mg/day (Newport et al. 2016).

Prenatal pharmacokinetic data are limited. High rates of placental transfer (i.e., umbilical cord concentrations in excess of maternal concentrations) have been reported for venlafaxine (Hendrick et al. 2003) and for its active metabolite desvenlafaxine (Hendrick et al. 2003; Rampono et al. 2009). Duloxetine has a single case report of a cord-to-maternal serum concentration ratio of 0.12, which suggests a low rate of placental transfer (Boyce et al. 2011).

Lactation data also remain limited. Best studied are venlafaxine/desvenlafaxine, for which three studies (Ilett et al. 1998; Newport et al. 2009; Rampono et al. 2011) encompassing 26 mother-infant nursing dyads have reported infant dosages that were 6.8%-8.1% of maternal dosages, which is within the notional 10% presumed safety level (Hendrick et al. 2003; Rampono et al. 2009). A single case report and a small case series of six women receiving duloxetine therapy during lactation described relative infant doses of less than 1% (Boyce et al. 2011; Lobo et al. 2008). The sole report of bupropion in nursing infants noted that the drug could not be detected in the plasma of a nursing infant (Briggs et al. 1993). Five studies totaling 55 neonates exposed to mirtazapine have reported no adverse outcomes and a low relative infant dose (Aichhorn et al.

2004; [Klier et al. 2007](#); [Kristensen et al. 2007](#); [Smit et al. 2015](#); [Tonn et al. 2009](#)). No lactation data have been published for vilazodone or vortioxetine.

## Tricyclic Antidepressants

Before the introduction of the SSRIs, TCAs were widely used during pregnancy and lactation. No clear association has been established between TCA exposure and congenital malformations. Early studies raised concerns about limb anomalies ([Barson 1972](#); [Elia et al. 1987](#); [McBride 1972](#)), but a meta-analysis by [Altshuler et al. \(1996\)](#) identified a congenital malformation incidence of only 3.14% ( $n=13$ ) among 414 infants exposed to a TCA during the first trimester. A data review from the European Network of Teratology Information Services and the United Kingdom's General Practice Research Database found similar rates of malformation after TCA exposure ([McElhatton et al. 1996](#); [Vasilakis-Scaramozza et al. 2013](#)). Moreover, no adverse neurodevelopmental effects were reported in two studies involving 126 children with prenatal TCA exposure ([Nulman et al. 1997a, 2002](#)).

Few data exist regarding the acute effects of TCA exposure on fetal and neonatal well-being. There are case reports of fetal tachycardia and neonatal symptoms including tachypnea, tachycardia, cyanosis, irritability, hypertonia, clonus, and spasm ([Eggermont 1973](#); [ter Horst et al. 2012](#)). A small ( $n=18$ ) prospective study found no evidence of increased complications during labor and delivery but did report transient withdrawal symptoms among TCA-exposed neonates ([Misri and Sivertz 1991](#)).

TCAs have been widely used during lactation. The only adverse event reported to date is respiratory depression in a nursing infant exposed to doxepin, leading the authors to conclude that doxepin should be avoided but that most TCAs are safe for use during breast feeding ([Matheson et al. 1985](#)). This clinical finding is paralleled by pharmacokinetic data indicating that whereas all TCAs are excreted in breast milk, infant plasma concentrations are considerably higher for doxepin than for other TCAs (for a review, see [Wisner et al. 1996b](#)).

## Monoamine Oxidase Inhibitors

Although the monoamine oxidase inhibitors (MAOIs) were introduced almost 50 years ago, reproductive safety data are sparse. The utility of MAOIs during pregnancy and lactation is severely limited by the potential for hypertensive crisis, which necessitates dietary constraints and avoidance of numerous medications that are commonly used during pregnancy (e.g., pseudoephedrine) or labor and delivery (e.g., meperidine).

---

## Mood Stabilizers

---

### Lithium

Early retrospective data suggested that lithium exposure was associated with a 400-fold increase in cardiac malformations—specifically, a defect of the tricuspid valve known as Ebstein’s anomaly ([Nora et al. 1974](#); [Weinstein](#)

and Goldfield 1975). However, a subsequent meta-analysis calculated the risk ratio for cardiac malformations as 1.2–7.7 and the risk ratio for overall congenital malformations as 1.5–3.0 (Cohen et al. 1994). Altshuler et al. (1996) estimated that the risk of Ebstein’s anomaly after prenatal lithium exposure rises from 1 in 20,000 to 1 in 1,000. A recent study indicated that lithium exposure in utero is associated with a higher rate of cardiovascular malformations but not of all major congenital malformations (Diav-Citrin et al. 2014). Additional studies (albeit small ones) also failed to confirm the early estimates regarding lithium’s teratogenic potential (Friedman and Polifka 2000; Jacobson et al. 1992; Källén and Tandberg 1983). Laboratory animal studies had indicated that neurobehavioral alterations also might be a concern for prenatal lithium exposure, but two studies of school-age children exposed to lithium during gestation found no evidence of adverse neurobehavioral sequelae (Schou 1976; van der Lugt et al. 2012).

The continued recommendation for prenatal assessment for fetal anomalies in women taking lithium includes a fetal echocardiogram between weeks 18 and 20 of gestation. In the event of unplanned conception during lithium therapy, the decision to continue or discontinue lithium should be informed by the severity and course of the patient’s illness and the time point in gestation when the exposure comes to attention. Discontinuing lithium therapy after cardiogenesis is complete, at approximately 9–11 weeks’ gestation, may be ill advised.

Lithium’s low therapeutic index raises concerns about acute perinatal toxicities. Lithium exposure later in gestation can result in fetal and neonatal cardiac arrhythmias (Wilson et al. 1983), hypoglycemia and

nephrogenic diabetes insipidus ([Mizrahi et al. 1979](#)), thyroid dysfunction ([Karlsson et al. 1975](#)), polyhydramnios, premature delivery, and floppy infant syndrome ([Llewellyn et al. 1998](#)). Neonatal symptoms of lithium toxicity, including flaccidity, lethargy, and poor suck reflexes, may persist for more than 7 days ([Woody et al. 1971](#)).

In a pooled analysis of lithium placental passage and neonatal outcomes ([Newport et al. 2005](#)), we determined that 1) higher neonatal lithium concentrations were associated with significantly lower Apgar scores, longer hospital stays, and higher rates of CNS and neuromuscular complications; 2) umbilical cord (i.e., fetal) plasma concentrations were uniformly equivalent to maternal concentrations, suggesting that lithium rapidly equilibrates across the placenta; and 3) withholding lithium therapy for 24–48 hours prior to delivery resulted in a 0.28 mEq/L reduction in maternal (and presumably fetal) lithium concentrations, thereby likely improving neonatal outcomes.

The physiological alterations of pregnancy are of particular importance in the perinatal management of lithium. Changes in renal clearance over the course of pregnancy and the potential for abrupt volume changes during delivery as a result of copious diaphoresis and the loss of blood and amniotic fluid mandate careful monitoring of lithium levels during pregnancy and especially at delivery. Furthermore, nonsteroidal anti-inflammatory drugs, which inhibit renal clearance of lithium, should be avoided in mother and infant alike during the early postpartum period.

The existing database regarding lithium and lactation encompasses 25 mother–infant nursing dyads ([Bogen et al. 2012](#); [Fries 1970](#); [Schou and Amdisen 1973](#); [Skausig and](#)

Schou 1977; Sykes et al. 1976; Tunnessen and Hertz 1972; Viguera et al. 2007a; Weinstein and Goldfield 1969; Woody et al. 1971). Adverse events, including lethargy, hypotonia, hypothermia, cyanosis, electrocardiogram changes, poor feeding, slow growth, gross and fine motor delay, and elevated thyroid-stimulating hormone levels, were reported in five (16%) of these children (Bogen et al. 2012; Skausig and Schou 1977; Tunnessen and Hertz 1972; Viguera et al. 2007a; Woody et al. 1971), including one infant who developed frank lithium toxicity with a serum concentration of 1.4 mEq/L, which was double the maternal level (Skausig and Schou 1977). The American Academy of Pediatrics (American Academy of Pediatrics Committee on Drugs 2001) discourages the use of lithium during lactation. The largest pharmacokinetic study of lithium in lactation reported a milk-to-plasma ratio of 0.53 and an infant-to-maternal plasma ratio of 0.24 (Viguera et al. 2007a). In other studies, nursing infants have had lithium concentrations generally ranging from 5% to 65% of maternal levels (Bogen et al. 2012; Fries 1970; Kirksey and Groziak 1984; Schou and Amdisen 1973; Sykes et al. 1976; Tunnessen and Hertz 1972; Weinstein and Goldfield 1969), excluding the lone infant whose serum concentration was 200% of the maternal concentration (Skausig and Schou 1977). Because dehydration can increase vulnerability to lithium toxicity, the hydration status of nursing infants of mothers taking lithium should be carefully monitored (Llewellyn et al. 1998).

## Valproate (Valproic Acid)

Prenatal exposure to valproate has been associated with numerous congenital malformations (rate of 6.7% for overall congenital malformations; [Campbell et al. 2014](#)), including neural tube defects ([Bjerkedal et al. 1982](#); [Centers for Disease Control 1992](#); [Jäger-Roman et al. 1986](#); [Lindhout and Schmidt 1986](#)), craniofacial anomalies ([Assencio-Ferreira et al. 2001](#); [Lajeunie et al. 1998, 2001](#); [Paulson and Paulson 1981](#)), limb abnormalities ([Rodríguez-Pinilla et al. 2000](#)), cardiovascular anomalies ([Dalens et al. 1980](#); [Koch et al. 1983](#); [Sodhi et al. 2001](#); [Veiby et al. 2014](#)), and hypospadias ([Veiby et al. 2014](#)). Valproate exposure prior to neural tube closure, during the fourth week of gestation, confers a 1%–2% risk of spina bifida, which is 10–20 times greater than the risk in the general population ([Bjerkedal et al. 1982](#); [Centers for Disease Control 1992](#); [Rosa 1991](#)). One meta-analysis placed the risk of neural tube defects even higher, at 3.8%, with particular vulnerability for the infants of women whose daily dosage exceeded 1,000 mg ([Samrén et al. 1997](#)). Other studies support this dose-response relationship ([Canger et al. 1999](#); [Kaneko et al. 1999](#); [Omtzigt et al. 1992](#); [Samrén et al. 1999](#); [Tomson et al. 2011, 2015](#)), leading one group to recommend that daily dosages not exceed 1,000 mg and that maternal serum concentrations not exceed 70 µg/mL to reduce the risk of malformations ([Kaneko et al. 1999](#)). In a case-control study examining the incidence of limb malformations in a cohort of more than 44,000 children, 67 of whom were exposed to valproate in the first trimester, [Rodríguez-Pinilla et al. \(2000\)](#) reported an OR of 6.17 for limb abnormalities among children exposed to valproate and estimated the risk of limb abnormalities from valproate exposure at 0.42%.

A *fetal valproate syndrome* was initially reported by [DiLiberti et al. \(1984\)](#) and subsequently confirmed by other investigators ([Ardinger et al. 1988](#); [Martínez-Frías 1990](#); [Winter et al. 1987](#)). The phenotypic attributes of fetal valproate syndrome include stereotypical facial features such as bifrontal narrowing, midface hypoplasia, a broad nasal bridge, a short nose with anteverted nares, epicanthal folds, micrognathia, a shallow philtrum, a thin upper lip, and a thick lower lip ([McMahon and Braddock 2001](#); [S.J. Moore et al. 2000](#)). Many of the congenital malformations previously associated with valproate exposure have been recognized as attributes of fetal valproate syndrome ([McMahon and Braddock 2001](#)). Valproate's antagonism of folate activity may underlie the risk of both spina bifida and fetal valproate syndrome. A case-control study comparing 57 children with fetal anticonvulsant syndromes, 46 of whose mothers were given valproate, with 152 control children found a significantly higher rate of homozygosity for a mutation in the gene for methylenetetrahydrofolate reductase (*MTHFR*), a key enzyme in folate metabolism, in the valproate-exposed children ([Dean et al. 1999](#)).

Neurodevelopmental outcomes associated with prenatal valproate exposure are equally of concern. A review found that developmental delay was evident in 20% and intellectual disability in 10% of children exposed to valproate monotherapy prenatally ([Kozma 2001](#)). An interim report from a prospective multicenter investigation of the neurodevelopmental effects of prenatal antiepileptic drug exposure noted that 24% of 2-year-olds with prenatal valproate exposure had mental developmental indexes of less than 70, more than double the rate associated with other antiepileptic drugs ([Meador et al. 2006](#)). More recent studies have consistently shown deleterious

neurodevelopmental effects from prenatal valproate exposure ([Baker et al. 2015](#); [Cohen et al. 2013](#); [Meador et al. 2009, 2013](#); [Shallcross et al. 2011](#); [Veiby et al. 2013](#)), with particular consequences for verbal cognition ([McVearry et al. 2009](#); [Meador et al. 2011](#); [Nadebaum et al. 2011a, 2011b](#)). Retrospective reports indicate that varying degrees of cognitive impairment may be present in children manifesting the physical sequelae of fetal valproate syndrome ([Adab et al. 2001](#); [Gaily et al. 1990](#); [Moore et al. 2000](#)). Fetal valproate syndrome also has been associated with autism spectrum disorders ([Bescoby-Chambers et al. 2001](#); [Christensen et al. 2013](#); [Moore et al. 2000](#); [Williams and Hersh 1997](#); [Williams et al. 2001](#); [Wood et al. 2015](#)).

Valproate exposure during gestation is also associated with risks for numerous fetal and neonatal toxicities, including hepatotoxicity ([Kennedy and Koren 1998](#)), coagulopathies ([Mountain et al. 1970](#)), and neonatal hypoglycemia ([Ebbesen et al. 2000](#); [Thisted and Ebbesen 1993](#)). Ten of 13 infants who had neonatal hypoglycemia after prenatal valproate exposure developed withdrawal symptoms—including irritability, jitteriness, hypertonia, seizures, and vomiting—that began 12–24 hours after delivery and lasted up to 1 week ([Ebbesen et al. 2000](#)).

Pharmacokinetic studies in women with epilepsy have reported that maternal valproate concentrations steadily decline over the course of pregnancy, falling to levels as much as 50% lower than preconception concentrations ([Yerby et al. 1990, 1992](#)). Consistent findings from other studies indicate that valproate is more rapidly cleared during gestation, and especially during the final month of pregnancy ([Nau et al. 1982b](#); [Otani 1985](#); [Philbert et al. 1985](#)). Dosage increases during pregnancy therefore may be required to maintain therapeutic efficacy. Valproate

readily crosses the human placenta, with umbilical cord concentrations at delivery equal to or slightly higher than maternal concentrations ([Froescher et al. 1984b](#); [Philbert et al. 1985](#); [Yerby et al. 1990, 1992](#)).

The database regarding valproate and lactation includes 41 mother–infant nursing dyads ([Alexander 1979](#); [Bardy et al. 1982a](#); [Dickinson et al. 1979](#); [Froescher et al. 1981](#); [Nau et al. 1981](#); [Piontek et al. 2000](#); [Stahl et al. 1997](#); [Tsuru et al. 1988](#); [von Unruh et al. 1984](#); [Wisner and Perel 1998](#)). From these cases, only one adverse event, thrombocytopenia and anemia in an infant, has been reported ([Stahl et al. 1997](#)). The pharmacokinetic data indicate that valproate milk-to-plasma ratios are uniformly low and that serum concentrations of nursing infants are 2%–40% of maternal concentrations ([Alexander 1979](#); [Bardy et al. 1982a](#); [Piontek et al. 2000](#); [Stahl et al. 1997](#); [von Unruh et al. 1984](#); [Wisner et al. 1996b](#)). In a study of the neurobehavioral effects of valproate exposure during lactation, [Meador et al. \(2014\)](#) found no adverse effects on cognitive functions.

In summary, prenatal valproate use raises grave safety concerns. In women of childbearing age, valproate should never be used except as a treatment of last resort. If valproate must be used during pregnancy, its risk may be reduced by being careful not to exceed 1,000 mg/day or a serum concentration of 70 µg/mL. Folate supplementation (4–5 mg/day) is also recommended, although no definitive evidence indicates that it reduces the risk of valproate-associated anomalies. All women of childbearing potential who are treated with valproate should receive concomitant folate supplementation, regardless of whether they plan to conceive. The preliminary evidence that aspects of fetal valproate syndrome other than neural tube defects may be

associated with valproate's antagonism of folate metabolism suggests that folate supplementation should be administered not only in the first trimester but also throughout gestation. Because of the potential for valproate-associated neonatal coagulopathies, oral vitamin K supplementation (10–20 mg/day) may be considered during the final month of gestation. Prenatal surveillance for congenital abnormalities should include maternal serum  $\alpha$ -fetoprotein, fetal echocardiography, and a level 2 ultrasound at approximately 16–18 weeks' gestation. Finally, genetic screening of women taking valproate for mutations in the *MTHFR* gene warrants future consideration.

In contrast to the marked risks of its use during pregnancy, valproate therapy during lactation appears to be well tolerated by nursing infants. Nevertheless, periodic assays of platelet counts and serum liver enzymes in nursing infants are recommended because the neurodevelopmental effect of nursing exposure to valproate is unclear.

## Carbamazepine

Carbamazepine is associated with many of the same risks as valproate during gestation, although in many cases with less frequency or severity. For example, first-trimester carbamazepine exposure is associated with a 0.5%–1.0% risk of neural tube defects ([Rosa 1991](#)), which is approximately half that seen with valproate exposure ([Lindhout and Schmidt 1986](#); [Rosa 1991](#)). A meta-analysis of five prospective studies encompassing 1,255 prenatal exposures indicated that carbamazepine exposure in utero

is associated with an increased risk of neural tube defects, cleft palate, cardiovascular abnormalities, and urinary tract anomalies ([Matalon et al. 2002](#)). The European Surveillance of Congenital Anomalies (EUROCAT) study ([Jentink et al. 2010](#)), a large case-control investigation, reported that carbamazepine exposure was associated with an increased risk of spina bifida (OR=2.6) only. The Australian Register of Antiepileptic Drugs in Pregnancy showed that carbamazepine exposure in utero was associated with renal tract abnormalities ([Vajda et al. 2013](#)). An epidemiological study indicated that periconceptional folate supplementation was associated with a lower rate of neural tube defects among the children of women taking carbamazepine during pregnancy ([Hernández-Díaz et al. 2001](#)).

A *fetal carbamazepine syndrome*—manifested by a short nose, long philtrum, epicanthal folds, hypertelorism, upslanting palpebral fissures, and fingernail hypoplasia—has been described ([Jones et al. 1989](#)), and in one study, the phenotypic characteristics of this syndrome were observed in 6 of 47 children prenatally exposed ([Ornoy and Cohen 1996](#)). Other studies have confirmed the association with facial anomalies ([Moore et al. 2000](#); [Nulman et al. 1997b](#); [Scolnik et al. 1994](#); [Wide et al. 2000](#)), but one of these studies found similar facial abnormalities among children born to women with epilepsy who were untreated during pregnancy ([Nulman et al. 1997b](#)). There has been an isolated case report of phocomelia (i.e., absence or underdevelopment of limbs) in an infant with in utero exposure ([Dursun et al. 2012](#)).

Data regarding the neurodevelopmental sequelae of prenatal carbamazepine exposure have been mixed. Some studies reported developmental delay in up to 20% of

children with fetal carbamazepine syndrome (Jones et al. 1989; Meador et al. 2011; Moore et al. 2000; Ornoy and Cohen 1996; Veiby et al. 2013), but others did not find that association (Gaily et al. 1990; Scolnik et al. 1994; van der Pol et al. 1991; Wide et al. 2000). Recent systematic studies generally have found no evidence of developmental delay in children exposed to carbamazepine in utero (Baker et al. 2015; McVearry et al. 2009; Meador et al. 2006, 2009, 2011; Nadebaum et al. 2011b).

Potential fetal/neonatal toxicities associated with carbamazepine exposure include blood dyscrasias, coagulopathies, skin reactions, and hepatotoxicity. Most of these risks remain theoretical, although neonatal hepatotoxicity has been reported in a carbamazepine-exposed infant (Frey et al. 2002).

Pharmacokinetic studies of carbamazepine clearance during gestation have yielded mixed results. Some investigators have reported significant increases in carbamazepine clearance during the third trimester (Battino et al. 1982; Dam et al. 1979; Lander et al. 1981), but others have found no changes in clearance (Bardy et al. 1982b; Johnson et al. 2014; Otani 1985; Reisinger et al. 2013; Yerby et al. 1985). Placental pharmacokinetic studies indicate that the placental transfer of carbamazepine is lower than that of other anticonvulsants (Nau et al. 1982a; Yerby et al. 1990, 1992), with umbilical cord-to-maternal plasma ratios of 0.5–0.8 (Nau et al. 1982a).

The literature on carbamazepine and lactation encompasses 12 published reports and 144 mother-infant nursing pairs (Brent and Wisner 1998; Frey et al. 1990, 2002; Froescher et al. 1984a; Kaneko et al. 1982; Kok et al. 1982; Kuhnz et al. 1983; Merlob et al. 1992; Niebyl et al. 1979; Pynnönen and Sillanpää 1975; Pynnönen et al. 1977;

Wisner and Perel 1998), representing the most extensive data set for any mood stabilizer in lactation. Included are 8 reports of adverse events: 1 drowsy, irritable infant with an undetectable serum concentration of carbamazepine (Kok et al. 1982); 2 “hyperexcitable” infants in whom carbamazepine levels were not reported (Kuhnz et al. 1983); 2 infants with cholestatic hepatitis in whom carbamazepine levels were not reported (Frey et al. 1990, 2002); 1 infant with poor nursing effort (Froescher et al. 1984a); 1 infant with an increased serum concentration of  $\gamma$ -glutamyl transpeptidase (GGT) but no overt clinical sequelae whose serum concentration was 33% of the maternal concentration (Merlob et al. 1992); and 1 infant with a seizurelike phenomenon whose carbamazepine level was 8% of the maternal level (Brent and Wisner 1998). Serum carbamazepine concentrations in the 8 nursing infants in whom these levels were assessed ranged from undetectable to 65% of the maternal level (Brent and Wisner 1998; Kok et al. 1982; Merlob et al. 1992; Pynnönen and Sillanpää 1975; Pynnönen et al. 1977; Wisner and Perel 1998).

Although the risks associated with prenatal carbamazepine exposure are marginally better than those for valproate exposure, the clinical recommendations are quite similar. Carbamazepine should be avoided in pregnancy, especially during the first trimester. Folate supplementation (4–5 mg/day) is also recommended, not only during gestation but also throughout the reproductive years because of the high prevalence of inadvertent conception in the United States. Women taking carbamazepine during gestation should receive prenatal surveillance for congenital abnormalities, including maternal serum  $\alpha$ -fetoprotein, fetal echocardiography, and

a level 2 ultrasound at approximately 16–18 weeks' gestation. Carbamazepine has by far the most extensive database for mood stabilizers in lactation, but reports of hepatic dysfunction in nursing infants certainly raise concern. Thus, periodic assays of blood counts and serum liver enzymes of nursing infants are recommended.

## Lamotrigine

Reproductive safety data for lamotrigine have rapidly accrued during the past decade and compare favorably with safety data for other mood stabilizers. The overall risk of major fetal malformations following first-trimester prenatal exposure to lamotrigine is 2.6% (207 per 7,951 exposures) ([Campbell et al. 2014](#); [Cunnington et al. 2011](#); [Dominguez-Salgado et al. 2004](#); [GlaxoSmithKline 2007](#); [Holmes et al. 2006](#); [Meador et al. 2006](#); [Mølgaard-Nielsen and Hviid 2011](#); [Morrow et al. 2006](#); [Sabers et al. 2004](#); [Vajda et al. 2003](#)), a risk that is within the range associated with births not involving drug exposures. A report by the North American Pregnancy Registry ([Holmes et al. 2006](#)) noted a relatively high rate of midline facial clefts (0.89% of 564 exposures); however, the collective rate of orofacial clefts in the other registries was only 0.10% (3 per 2,956 exposures) ([Dominguez-Salgado et al. 2004](#); [GlaxoSmithKline 2007](#); [Meador et al. 2006](#); [Mølgaard-Nielsen and Hviid 2011](#); [Morrow et al. 2006](#); [Sabers et al. 2004](#); [Vajda et al. 2003](#)). Furthermore, the EUROCAT case-control study, encompassing 5,511 children with orofacial clefts and 80,052 children without clefts, reported an adjusted OR of 0.67 for clefts with lamotrigine exposure ([Dolk et al. 2008](#)). The U.K. Epilepsy and Pregnancy

Register reported a higher risk of malformations at maternal dosages exceeding 200 mg/day ([Morrow et al. 2006](#)), although this finding was not confirmed in subsequent analyses ([GlaxoSmithKline 2007](#); [Mølgaard-Nielsen and Hviid 2011](#)). Despite these reassuring findings, folate supplementation is recommended for all women of childbearing age taking any antiepileptic drug, including lamotrigine. Prospective neurodevelopmental data have been consistently favorable among children with prenatal lamotrigine exposure ([Baker et al. 2015](#); [McVearry et al. 2009](#); [Meador et al. 2006, 2009, 2011](#); [Nadebaum et al. 2011b](#)).

Numerous pharmacokinetic studies have reported that lamotrigine clearance steadily increases across gestation ([de Haan et al. 2004](#); [Fotopoulou et al. 2009](#); [Franco et al. 2008](#); [Pennell et al. 2004, 2008](#); [Petrenaite et al. 2005](#); [Polepally et al. 2014](#); [Reisinger et al. 2013](#); [Tran et al. 2002](#)). These studies are limited by polytherapy with other anticonvulsants, which are known to alter the metabolism of lamotrigine. It is unclear whether dosage changes would be necessary to maintain mood stability in patients with bipolar disorder and whether the adjunctive agents commonly used in the treatment of bipolar disorder would have similar effects on lamotrigine metabolism. Studies in patients taking lamotrigine also report that its rate of clearance abruptly declines after delivery ([Ohman et al. 2000](#); [Pennell et al. 2004](#); [Polepally et al. 2014](#); [Tran et al. 2002](#)). Therefore, dosage reductions may be necessary after delivery to avoid maternal symptoms of lamotrigine toxicity, such as dizziness, nausea and vomiting, and diplopia ([Tran et al. 2002](#)). Published reports on the placental passage of lamotrigine indicate that lamotrigine concentrations in fetal circulation at delivery are equal to

maternal concentrations ([Myllynen et al. 2003](#); [Ohman et al. 2000](#); [Paulzen et al. 2015](#); [Sathanandar et al. 2000](#); [Tomson et al. 1997](#)). There have been no reports of acute adverse events observed in neonates exposed to lamotrigine.

Reports regarding lamotrigine and lactation ([Clark et al. 2013](#); [GlaxoSmithKline 2007](#); [Liporace et al. 2004](#); [Newport et al. 2008c](#); [Nordmo et al. 2009](#); [Ohman et al. 2000](#); [Page-Sharp et al. 2006](#); [Rambeck et al. 1997](#); [Tomson et al. 1997](#)) collectively encompass 60 mother-infant nursing dyads. The only reported adverse event was an apneic episode in a nursing infant whose mother was taking lamotrigine 850 mg/day ([Nordmo et al. 2009](#)). Seven other infants were observed to have a benign thrombocytosis ([Newport et al. 2008b](#)). In the largest ( $n=30$ ) of these studies ([Newport et al. 2008b](#)), the mean milk-to-plasma ratio was 41.3%, the relative infant dose equaled 9.2%, and the infant-to-maternal plasma ratio equaled 18.3%. Long-term neurobehavioral outcomes have not been studied in nursing infants exposed to lamotrigine.

---

## Antipsychotics

---

### Second-Generation Antipsychotics

Commonly prescribed antipsychotic medications, as well as agents used to treat the side effects of first-generation antipsychotics (FGAs), are covered in [Chapters 24–35](#). The second-generation antipsychotics (SGAs) have supplanted the FGAs as first-line medications for psychotic disorders and are also used for other psychiatric indications,

including bipolar disorder, anxiety disorders, and treatment-resistant depression. Despite rapidly expanding use, the reproductive safety database regarding SGAs remains limited. A recent study that used a national pregnancy registry for SGAs reported an OR of 1.25 (95% CI=0.13–12.13) for major malformations in exposed infants compared with nonexposed infants ([Cohen et al. 2015](#)). A neurobehavioral outcome study identified a transient delay in cognitive, motor, social-emotional, and adaptive behavior in SGA-exposed infants that resolved by age 12 months ([Peng et al. 2013](#)).

Even though some data have been reassuring, the small volume of SGA data to date precludes definitive conclusions about their reproductive safety. Therefore, the routine use of SGAs during pregnancy and lactation cannot yet be recommended. Nonetheless, if a woman who is taking an SGA inadvertently conceives, a comprehensive risk–benefit assessment may indicate that continuing the SGA (to which the fetus has already been exposed) during gestation is preferable to switching to an FGA (to which the fetus has not yet been exposed).

## **Clozapine**

Reproductive safety data for clozapine, the oldest of the SGAs, are limited to case reports ([Barnas et al. 1994](#); [Di Michele et al. 1996](#); [Kornhuber and Weller 1991](#); [Moreno-Bruna et al. 2012](#); [Waldman and Safferman 1993](#)), case series ([McKenna et al. 2005](#); [Stoner et al. 1997](#); [Tenyi and Tixler 1998](#)), and a retrospective review ([Dev and Krupp 1995](#)), collectively encompassing 80 children exposed to clozapine during pregnancy and/or lactation. Adverse sequelae associated with in utero clozapine therapy include maternal gestational diabetes ([Dickson and Hogg 1998](#));

several minor anomalies, including cephalohematoma, hyperpigmentation folds, and a coccygeal dimple, in an infant (Stoner et al. 1997); delayed peristalsis (Moreno-Bruna et al. 2012); transient low-grade fever in an infant also exposed to lithium (Stoner et al. 1997); and floppy infant syndrome in a newborn also exposed to lorazepam (Di Michele et al. 1996). In a review of 61 children exposed to clozapine prenatally, Dev and Krupp (1995) reported 5 cases of congenital malformations and 5 cases of neonatal syndromes; however, many of these mothers were taking other psychotropic medications during pregnancy. A recent study of neurodevelopmental consequences of prenatal exposure to SGAs reported higher rates of developmental delay at ages 2 months and 6 months among clozapine-exposed infants compared with infants exposed to other SGAs (Shao et al. 2015). The only reported case of clozapine use during lactation noted no adverse effects on the nursing infant (Kornhuber and Weller 1991).

The only investigation of the perinatal pharmacokinetics of clozapine found elevated concentrations in fetal serum and breast milk compared with concentrations in maternal serum and amniotic fluid (Barnas et al. 1994), leading the authors to conclude that clozapine accumulates in fetal circulation and breast milk. Although no cases of agranulocytosis have been reported in clozapine-exposed infants, this potential risk and the requisite laboratory monitoring limit the utility of clozapine during the peripartum.

## **Olanzapine**

A published birth registry of 23 prospectively ascertained olanzapine-exposed pregnancies from the Lilly Worldwide Pharmacovigilance Safety Database reported no major

malformations, 13% spontaneous abortions, 5% preterm deliveries, and 5% fetal deaths ([Goldstein et al. 2000](#)). In a subsequent examination of the same database, 610 prospectively identified pregnancies exposed to olanzapine resulted in 10% premature births, 9% spontaneous abortions, 8% perinatal conditions (i.e., an adverse event occurring within 7 days of birth), and 4% congenital anomalies ([Brunner et al. 2013](#)). A prospective study comparing outcomes among 151 pregnant women with SGA exposure (olanzapine,  $n=60$ ; risperidone,  $n=49$ ; quetiapine,  $n=36$ ; clozapine,  $n=6$ ) with outcomes among 151 pregnant control subjects reported no differences in rates of spontaneous abortion, stillbirth, major malformations, prematurity, or low birth weight ([McKenna et al. 2005](#)). In this study, one SGA-exposed child (olanzapine) was observed to have major malformations (a series of midline defects including an oral cleft, encephalocele, and aqueductal stenosis). A recent meta-analysis reported a malformation rate of 3.5% among 1,090 olanzapine-exposed infants, a rate that compares favorably to rates with other SGAs ([Ennis and Damkier 2015](#)).

In a study of antipsychotic placental passage rates and neonatal outcomes ([Newport et al. 2007a](#)), umbilical cord concentrations in olanzapine-exposed neonates ( $n=14$ ) were 72.1% of maternal concentrations. In this study, there was a trend toward higher rates of low birth weight (30.8%;  $P<0.06$ ) and neonatal intensive care unit admission (30.8%;  $P<0.09$ ) among neonates exposed to olanzapine compared with those exposed to the other antipsychotics.

Case reports of 39 infants exposed to olanzapine during lactation with no evidence of infant toxicity currently appear in the literature ([Croke et al. 2002](#); [Friedman and Rosenthal 2003](#); [Gardiner et al. 2003](#); [Gilad et al. 2011](#);

[Goldstein et al. 2000](#); [Kirchheiner et al. 2000](#); [Whitworth et al. 2010](#)). The Lilly Safety Database reported on 62 breastfeeding mother-infant dyads with a 15.6% rate of adverse events, identified as somnolence, irritability, tremors, and insomnia ([Brunner et al. 2013](#)). Pharmacokinetic studies of olanzapine exposure during lactation have reported that plasma concentrations were undetectable in infants during nursing ([Gardiner et al. 2003](#); [Kirchheiner et al. 2000](#); [Stiegler et al. 2014](#)) and that the median infant daily dosage via breast feeding was approximately 0.7%–1.8% of the maternal dosage ([Ambresin et al. 2004](#); [Aydin et al. 2015](#); [Brunner et al. 2013](#); [Croke et al. 2002](#); [Gardiner et al. 2003](#)).

## **Risperidone**

Prospective data on pregnancy outcomes following first-trimester risperidone exposure include a collective study of outcomes for several SGAs ([McKenna et al. 2005](#)) reporting no major malformations among 49 risperidone-exposed infants and a recent meta-analysis reporting a 5.1% malformation rate among 432 risperidone-exposed infants ([Ennis and Damkier 2015](#)). An additional study in 68 women with first-trimester exposure and known outcomes reported 9 (13.2%) spontaneous abortions, 1 (1.5%) stillbirth, and 2 (2.9%) children with major malformations ([Coppola et al. 2007](#)). No data on the neurodevelopmental effects of risperidone exposure during pregnancy or lactation are available.

Pharmacokinetic studies have reported placental passage concentrations among neonates ( $n=6$ ) of 49.2% ([Newport et al. 2007a](#)), milk-to-plasma ratios of less than 0.5 for risperidone and less than 0.88 for 9-hydroxyrisperidone ([Hill et al. 2000](#); [Ilett et al. 2004](#); [Weggelaar et al. 2011](#)),

and infant plasma concentrations ranging from 2.3% to 4.7% of maternal levels ([Ilett et al. 2004](#); [Weggelaar et al. 2011](#)).

## Quetiapine

The reproductive safety literature for first-trimester quetiapine exposure is limited to a case series of two successive pregnancies ([Grover and Madan 2012](#)), which reported healthy, full-term deliveries, and the [McKenna et al. \(2005\)](#) study, which reported no major malformations among 36 infants exposed to quetiapine. In the [Newport et al. \(2007a\)](#) study of antipsychotic placental passage, quetiapine concentrations among neonates ( $n=21$ ) were 23% of maternal concentrations. To our knowledge, this is the lowest placental passage rate ever reported for a psychotropic agent. No data are available on the neurodevelopmental effects of quetiapine exposure during pregnancy or lactation.

Three cases of quetiapine use during lactation following use during pregnancy estimated the nursing infant dosage at 0.09%–7.3% of the maternal daily dosage ([Lee et al. 2004](#); [Van Boekholt et al. 2015](#)).

## Aripiprazole

Reproductive safety data for aripiprazole include a case series of 86 mother–infant dyads that showed an increased risk of premature birth and fetal growth retardation but no increased risk of congenital malformations, miscarriages, preeclampsia, or gestational diabetes ([Bellet et al. 2015](#)). In addition, a recent meta-analysis reported a 5.0% malformation rate among 100 infants with first-trimester aripiprazole exposure ([Ennis and Damkier 2015](#)). A single

case report indicated poor respiratory effort at birth ([Watanabe et al. 2011](#)), and two case reports and a case series showed no adverse obstetrical or neonatal outcomes ([Gentile et al. 2011](#); [Lutz et al. 2010](#); [Windhager et al. 2014](#)).

Of the three case reports of aripiprazole use during lactation, the milk excretion profiles were questionable in two ([Lutz et al. 2010](#); [Schlotterbeck et al. 2007](#)), and the other reported a milk-to-plasma ratio of 0.051 ([Watanabe et al. 2011](#)). Placental transfer was 53.3%–54.7%, as shown in two reports of four mother–infant dyads ([Watanabe et al. 2011](#); [Windhager et al. 2014](#)).

## Other SGAs

Information about the use of other SGAs is scant. Use of ziprasidone, brexpiprazole, lurasidone, iloperidone, or asenapine during pregnancy has not been reported. A lone case report of use of paliperidone palmitate, the long-acting injectable formulation of paliperidone, during pregnancy (haloperidol was also used) indicated no adverse obstetrical outcomes ([Özdemir et al. 2015](#)).

Data concerning lactation were limited to a single case report of ziprasidone use during lactation that reported a milk-to-plasma ratio of 0.06 ([Schlotterbeck et al. 2009](#)).

## First-Generation Antipsychotics

In contrast to the SGAs, the FGAs have an extensive reproductive safety database addressing both somatic and neurobehavioral teratogenicity. Furthermore, the historical use of phenothiazine antipsychotics to treat pregnancy-associated emesis aids in separating the effects of

psychiatric illness and antipsychotic drugs on pregnancy outcome. Chlorpromazine, haloperidol, and perphenazine have received the greatest scrutiny, with no significant associations between these compounds and major malformations ([Goldberg and DiMascio 1978](#); [Hill and Stern 1979](#); [Nurnberg and Prudic 1984](#)).

In a study of 100 women taking haloperidol (mean dosage=1.2 mg/day) for hyperemesis gravidarum, no differences in gestational duration, fetal viability, or birth weight were noted ([Van Waes and Van de Velde 1969](#)). In a prospective study encompassing nearly 20,000 women receiving primarily phenothiazines for emesis, [Milkovich and van den Berg \(1976\)](#) found no significant association with neonatal survival rates or severe anomalies after controlling for maternal age, medication, and gestational age at exposure. Similar results have been obtained in several retrospective studies of women taking trifluoperazine for repeated abortions and emesis ([Moriarty and Nance 1963](#); [Rawlings et al. 1963](#)). In contrast, [Rumeau-Rouquette et al. \(1977\)](#) reported a significant association of major anomalies with prenatal exposure to aliphatic phenothiazines but not to piperazine- or piperidine-class agents. Reanalysis of the data obtained by [Milkovich and van den Berg \(1976\)](#) did find a significant risk of malformations associated with phenothiazine exposure in weeks 4 through 10 of gestation ([Edlund and Craig 1984](#)).

Neurobehavioral outcome studies encompassing 203 children exposed to FGAs during gestation detected no significant differences in IQ scores at age 4 years ([Kris 1965](#); [Slone et al. 1977](#)), although relatively low antipsychotic dosages were used by many women in these studies. Conversely, several laboratory animal studies

(Hoffeld et al. 1968; Ordy et al. 1966; Robertson et al. 1980), although not all (Dalleymagne and Weiss 1982), have identified persistent deficits in learning and memory among offspring prenatally exposed to FGA medications.

Beyond the teratogenic potential of the FGAs lies the possibility of fetal and infant toxicities such as neuroleptic malignant syndrome (James 1988) and extrapyramidal side effects (EPS) manifested by heightened muscle tone and increased rooting and tendon reflexes persisting for several months (Cleary 1977; Hill et al. 1966; O'Connor et al. 1981). Furthermore, prenatal exposure to FGAs has been associated with neonatal jaundice (Scokel and Jones 1962) and postnatal intestinal obstruction (Faltermann and Richardson 1980).

In our study of antipsychotic placental passage, neonatal haloperidol ( $n=13$ ) concentrations were 66% of maternal concentrations (Newport et al. 2007a).

In lactation, chlorpromazine is the most widely studied typical antipsychotic, with 7 infants exposed to chlorpromazine during nursing showing no developmental deficits at 16-month and 5-year follow-up evaluations (Kris and Carmichael 1957). However, 3 infants in another study whose mothers were prescribed both chlorpromazine and haloperidol showed evidence of developmental delay at 12-18 months (Yoshida et al. 1998b). Pharmacokinetic investigations of FGAs during lactation, including haloperidol (Stewart et al. 1980; Whalley et al. 1981; Yoshida et al. 1998b), trifluoperazine (Wilson et al. 1980; Yoshida et al. 1998b), perphenazine (Wilson et al. 1980), thioxanthenes (Matheson and Skjaeraasen 1988), and chlorpromazine (Yoshida et al. 1998b), have uniformly reported milk-to-plasma ratios of less than 1.0, although adequate control for distribution and time gradients was

lacking in these studies. One group postulated that the physicochemical properties of perphenazine could lead it to become “trapped” in breast milk ([Wilson et al. 1980](#)); however, this speculation is unconfirmed.

Fetal and infant exposure to any of the various agents available for the management of EPS (e.g., diphenhydramine, benztropine, amantadine) also raises concern. Results of the Collaborative Perinatal Project indicated that first-trimester exposure to diphenhydramine, the best studied of these medications, was associated with major and minor congenital anomalies ([Miller 1991](#); [Wisner and Perel 1988](#)). A case-control study found a significantly higher rate of prenatal diphenhydramine exposure among 599 infants with oral clefts than among 590 control infants ([Saxén 1974](#)). Despite these data, diphenhydramine is routinely used during pregnancy. Clinical studies of the teratogenic potential of benztropine and amantadine are lacking, although laboratory animal studies indicated that amantadine is associated with an elevated risk of congenital malformations ([Hirsch and Swartz 1980](#)). Perinatal toxicities, including neonatal intestinal obstruction after gestational exposure to benztropine ([Falterman and Richardson 1980](#)) and a possible neonatal diphenhydramine withdrawal syndrome manifested by tremulousness and diarrhea ([Parkin 1974](#)), also warrant concern.

In summary, FGAs have been widely used for more than 40 years, and the paucity of data linking these agents to either teratogenic or toxic effects suggests that their risks are minimal. In particular, piperazine phenothiazines (e.g., trifluoperazine, perphenazine) may have especially low teratogenic potential ([Rumeau-Rouquette et al. 1977](#)). Given the greater fetal risks associated with anticholinergic medications (e.g., diphenhydramine), their use should be

avoided if possible. Consequently, FGAs used during the antepartum period should be kept at the lowest effective dosage to minimize the need for adjunctive medications to manage EPS.

---

## Anxiolytics

---

Pharmacotherapy for anxiety disorders includes antidepressants, benzodiazepines, buspirone, and certain atypical antipsychotics.

### Benzodiazepines

A retrospective analysis of more than 100,000 women found that at least 2% were prescribed a benzodiazepine during gestation ([Bergman et al. 1992](#)). The earliest benzodiazepine teratogenicity studies reported an increased risk of oral clefts after in utero diazepam exposure ([Aarskog 1975](#); [Saxén 1975](#); [Saxén and Saxén 1975](#)), but later studies failed to confirm this association ([Ban et al. 2014](#); [Entman and Vaughn 1984](#); [Rosenberg et al. 1983](#); [Shiono and Mills 1984](#)). Prospective studies of first-trimester alprazolam exposure encompassing approximately 1,300 pregnancies indicated no excess of oral clefts or other birth defects ([Barry and St Clair 1987](#); [Schick-Boschetto and Zuber 1992](#); [St Clair and Schirmer 1992](#)), and a recent study of first-trimester exposure to diazepam and temazepam echoed this finding ([Ban et al. 2014](#)). A meta-analysis found that prenatal benzodiazepine exposure does confer an increased risk of oral clefts, although the absolute risk increased by only 0.01%

([Altshuler et al. 1996](#)). This conclusion is consistent with the findings of a later case-control study that found no difference in rates of prenatal benzodiazepine exposure between more than 38,000 infants with congenital anomalies and nearly 23,000 control children ([Eros et al. 2002](#)).

Although benzodiazepine teratogenicity data are somewhat mixed, benzodiazepine neonatal syndromes are well documented. Numerous groups have described a floppy infant syndrome characterized by hypothermia, lethargy, poor respiratory effort, and feeding difficulties following benzodiazepine exposure in late pregnancy ([Erkkola et al. 1983](#); [Fisher et al. 1985](#); [Haram 1977](#); [Källén and Reis 2012](#); [Kriel and Cloyd 1982](#); [McAuley et al. 1982](#); [Sanchis et al. 1991](#); [Speight 1977](#); [Woods and Malan 1978](#)). In a study of 53 infants with late-pregnancy lorazepam exposure, term infants whose mothers had taken oral lorazepam showed no evidence of toxicity other than a brief delay in establishing feeding, whereas preterm infants and term infants whose mothers had received larger intravenous doses of lorazepam had symptoms consistent with floppy infant syndrome ([Whitelaw et al. 1981](#)). Neonatal withdrawal syndromes, characterized by restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, and vomiting, have been described in infants whose mothers were taking alprazolam ([Barry and St Clair 1987](#)), chlordiazepoxide ([Athinarayanan et al. 1976](#); [Bitnun 1969](#); [Stirrat et al. 1974](#)), or diazepam ([Backes and Cordero 1980](#); [Mazzi 1977](#)). Benzodiazepine neonatal syndromes have been reported to persist for as long as 3 months after delivery (for a review, see [Miller 1991](#)).

Pharmacokinetic studies during pregnancy indicate that benzodiazepines readily traverse the placenta and with prolonged administration may accumulate in the fetus ([Mandelli et al. 1975](#); [Shannon et al. 1972](#)). For example, fetal concentrations of diazepam at delivery are typically higher than maternal concentrations ([Erkkola et al. 1974](#)). Because benzodiazepine metabolism is slower in the fetus than in the mother, it is understandable that an agent like diazepam (which has multiple active metabolites) might accumulate in the fetus. In addition, high concentrations of diazepam are sequestered in lipophilic fetal tissues, such as the brain, lungs, and heart ([Mandelli et al. 1975](#)). In contrast, fetal-to-maternal ratios of lorazepam (which has no active metabolites) are typically less than 1.0 ([Whitelaw et al. 1981](#)). Yet neonatal clearance of lorazepam is slow, with detectable levels evident 8 days after delivery ([Whitelaw et al. 1981](#)), and the clearance of chlordiazepoxide appears to be even slower ([Athinarayanan et al. 1976](#)).

Studies evaluating the neurobehavioral effects of prenatal benzodiazepine exposure are needed. A benzodiazepine exposure syndrome—consisting of growth retardation, dysmorphism, and mental and psychomotor retardation in infants ([Laegreid et al. 1987](#))—has been reported, although some investigators have disputed this finding ([Gerhardsson and Alfredsson 1987](#); [Winter 1987](#)). One group found no differences in the incidence of behavioral abnormalities at age 8 months or in IQ scores at age 4 years among children exposed to chlordiazepoxide during gestation ([Hartz et al. 1975](#)), and another group found no correlation between antenatal exposure and language competence at age 3 years ([Odsbu et al. 2015](#)). Nevertheless, a series of laboratory animal studies raised concerns that prenatal

benzodiazepine exposure may produce deficits in memory and learning ability ([Frieder et al. 1984](#); [Hassmannova and Myslivecek 1994](#); [Jaiswal and Bhattacharya 1993](#); [Myslivecek et al. 1991](#)).

[Buist et al. \(1990\)](#) concluded that benzodiazepines at low dosages present no contraindication to nursing. A recent retrospective cohort study found a sedation rate of 1.6% in infants exposed to benzodiazepines while breast feeding, but there was no association with maternal dosage ([Kelly et al. 2012](#)). Infants with impaired metabolic capacity may show sedation and poor feeding even with low maternal dosages ([Wesson et al. 1985](#)). Overall, benzodiazepines are associated with lower milk-to-plasma ratios than are other classes of psychotropics. For example, [Wretlind \(1987\)](#) found a milk-to-plasma ratio of 0.1–0.3 for oxazepam and calculated that the infant daily dosage via lactation is 1/1,000th of the maternal dosage. The percentage of the maternal dosage of lorazepam to which a nursing infant is exposed has been estimated to be 2.2% ([Summerfield and Nielsen 1985](#)).

In summary, benzodiazepines do not appear to carry a significant risk of somatic teratogenesis, but neurobehavioral sequelae remain obscure. Because benzodiazepines are associated with neonatal risks, they should be used judiciously and tapered before delivery if possible. Benzodiazepines should not be abruptly withdrawn during pregnancy. Because lorazepam and oxazepam are less dependent on hepatic metabolism, they theoretically have less potential for fetal accumulation during pregnancy. Finally, benzodiazepines can be safely administered, in judicious doses, during lactation. However, breast feeding should be discontinued if an infant

experiences sedation or other signs of benzodiazepine toxicity.

## Buspirone

Buspirone has garnered a unique, and arguably illogical, position within the psychotropic armamentarium. Although buspirone is labeled FDA Category B, published data are extremely limited. The only report of prenatal administration of buspirone identified 1 infant born with a major malformation among 14 infants with first-trimester buspirone exposure ([Wilton et al. 1998](#)). No published reports exist regarding buspirone's safety during lactation.

---

## Future Directions and General Recommendations

---

The development of prenatal and postnatal treatment guidelines is hampered by the haphazard accrual of clinical research data with inconsistent methodologies. Whereas clinical data have confirmed the teratogenic potential for only a few psychotropic agents, animal studies, which commonly use maternal concentrations exponentially higher than those seen in clinical care, show clear somatic and neurobehavioral teratogenicity ([Elia et al. 1987](#)). Such inconsistencies between clinical and preclinical data further confound efforts to construct reliable treatment recommendations. Similarly, advances in statistical methods and the accrual of data from a variety of sources have identified statistical findings that may have limited

relevance to clinical decision making ([Ranganathan et al. 2015](#)). Because pregnant and nursing women are generally excluded from clinical trials of pharmacological agents, definitive clarification with proper control groups is unlikely to be forthcoming in the near future. Consequently, clinical treatment decisions are made on the basis of incomplete or uncertain information.

## Informed Consent

Obtaining informed consent in the clinical decision cannot be overemphasized. Informed consent should include the following:

- Agreement on the primary treatment objective, which typically is to minimize potential harm to the fetus (Acceptance of and adherence to this objective will help reduce the potential for subsequent maternal self-recrimination.)
- Discussion of the availability, affordability, accessibility, and potential efficacy of nonpharmacological treatments
- Consideration of the likelihood and severity of illness without continued pharmacotherapy
- Review of the potential risks of untreated mental illness to the fetus and mother
- Review of the potential risks of fetal psychotropic exposure
- Acknowledgment that no risk-free alternative is available other than deciding not to conceive
- Acknowledgment that the understanding of risks remains incomplete (Ultimately, it is impossible to provide an exhaustive list of all risks for any given psychotropic

agent, but the evidence—or lack of evidence—for adverse effects should be reviewed.)

## Nonpsychotropic Treatment Strategies to Reduce In Utero Exposures

Nonpsychotropic treatments should focus on maximizing maternal health during pregnancy, such as prenatal vitamins; adequate hydration; daily exercise; and avoidance of alcohol, tobacco, caffeine, and illicit substances. Good evidence indicates that concomitant exposures, such as to tobacco, increase both obstetrical and neonatal risk. Nonpsychotropic treatment strategies also include psychotherapy alternatives appropriate during pregnancy and the postpartum period.

## Medication Selection

Medication selection requires several steps. Initial treatment planning for reproductive-age women with mental illness should include the potential pregnancy and future family planning. Notably, more than 45% of the pregnancies in the United States are unplanned, and knowledge of conception is often well into the organogenesis ([Finer and Zolna 2016](#); [Kost 2015](#)). Choosing initial pharmacotherapy with this in mind supports “new and improved=limited data.”

Psychotropic therapy is administered after knowledge of conception only when the clinician and patient agree that the risks to the fetus of untreated mental illness likely

exceed the risks of fetal psychotropic exposure. Consequently, both the safety and the efficacy of the psychotropic regimen are important considerations. A psychotropic agent is preferred if 1) it has previously been effective for the patient; 2) it has previously been well tolerated by the patient; 3) the fetus has already been exposed to it (i.e., the patient was taking the agent at knowledge of conception); and 4) it has a favorable reproductive safety profile. It is important to emphasize the potential hazards of switching agents during pregnancy or lactation. Changing medications generally should be avoided (unless well-defined risks are associated with the current regimen), because medication changes increase the number of medications to which the infant has been exposed, limit the clinician's ability to apply available safety information (e.g., virtually no data exist on concomitant or tandem multiple medication exposures), and may heighten the mother's vulnerability to illness.

## Dosage Management

Maintaining maternal emotional well-being is the goal of psychotropic treatment in the antepartum and postpartum periods. Partial or subtherapeutic treatment heightens risk by continuing to expose the mother and infant to both illness and medications. The minimum effective dosage should be maintained throughout treatment, and the clinician should remain mindful that dosage requirements may change during pregnancy. Similarly, clinicians and patients should be aware that dosage adjustment may not significantly alter fetal exposure during pregnancy (i.e., the fetus is exposed to the maternal plasma concentration, not

the maternal dosage). To minimize the potential for neonatal withdrawal and maternal toxicity after delivery, careful monitoring of side effects and serum concentrations may be indicated.

## Monitoring of Nursing Infants

Because clinical laboratory assays typically lack the sensitivity to detect the serum concentrations of nursing infants, infant plasma monitoring for psychotropic medications is not routinely indicated. If there is an index of suspicion that a child is experiencing an adverse effect from nursing exposure to a psychotropic medication, breast feeding should be discontinued. However, routine laboratory monitoring (e.g., blood counts, electrolytes, hepatic profiles) is required when nursing mothers are taking medications (e.g., lithium, valproate, carbamazepine) with low therapeutic indices or known systemic toxicities.

---

## Resources

---

For clinicians involved in the care of numerous women in their reproductive years, a valuable resource that includes an interactive e-book is *Drugs in Pregnancy and Lactation* by G.G. Briggs and R.K. Freeman.

Additional online resources include the following:

## CHAPTER 58

# Treatment of Psychiatric Emergencies

Steven J. Garlow, M.D., Ph.D.

Margaret B. Weigel, M.D.

Barbara D'Orio, M.D., M.P.A.

**Psychiatric emergencies** occur in many different situations and settings. While often managed in specialized crisis stabilization units, psychiatric emergencies occur in other locations, such as general medical/surgical units, outpatient clinics, general emergency departments, and other, nonclinical areas. The effective practice of emergency psychiatry requires a broad range of knowledge and clinical skills, including general and psychosomatic medicine, behavioral neurology, psychopharmacology, individual and family psychotherapy, and addiction medicine. In addition, a basic knowledge of forensic and legal issues is essential. With recent large-scale changes in mental health care delivery, including deinstitutionalization

and downsizing of inpatient mental health facilities, the role of an emergency psychiatrist has expanded dramatically. These changes impact not only psychiatric facilities but also general emergency medicine departments, with at least 6.3% of all emergency room visits being for psychiatric issues ([Larkin et al. 2005](#)). There were on average 420,000 emergency room visits per year for attempted suicide and self-injurious behaviors between 1993 and 2008. Ominously, the annual number of ED visits for suicide-related behaviors more than doubled from 1993–1996 (244,000/year) to 2005–2008 (538,000/year) ([Ting et al. 2012](#)). This trend continues unabated; the [Centers for Disease Control and Prevention \(2015\)](#) reports that there were 836,000 emergency department visits for self-inflicted injury in 2011.

Patients with emergent behavioral and psychiatric syndromes are often unable or unwilling to provide accurate historical details; therefore, the clinician must rely on collateral sources of information, including friends, family, and previous treatment providers. One consequence of this process of data collection is that absolute patient confidentiality, the standard of care in other clinical settings, is more tenuous. The Health Insurance Portability and Accountability Act (HIPAA) regulates all disclosures of Protected Health Information (PHI) by health care providers. In [2014, the U.S. Department of Health and Human Services](#) issued guidance on the implementation of HIPAA in the setting of psychiatric emergencies. In the context of a psychiatric emergency, the need to acquire critical information supersedes the individual's absolute right to privacy. The guiding principal is the determination of the clinician, based on professional judgment, that disclosure of certain PHI would be in the best interests of

the patient in that particular emergent situation. Disclosures to family, friends, and other care providers can be made if the patient does not object when informed of the proposed disclosure, or if (in the professional judgment of the clinician) the patient does not have capacity based on his or her mental status (examples being psychosis, substance intoxication, or unresponsive states). In emergent situations, resources such as medical records, friends, and relatives may provide critical data for diagnosis and treatment. There is no prohibition in HIPAA for a clinician to listen to information provided by family, friends, and other care providers or to read outside clinical records. This is one situation in which it is appropriate to stretch the boundaries of confidentiality in order to provide the best clinical care. The focus is on obtaining components of history and developing a treatment plan while not needlessly disclosing protected information, and only those disclosures absolutely necessary for the well-being of the patient should be made. There are other circumstances in which there is a mandated breach of confidentiality, which include a patient's risk of harm to self or others and the knowledge of child or elder abuse. HIPAA does not prevent these mandatory disclosures to protect the safety of the patient or others. Specific disclosure and third-party contact requirements vary by jurisdiction.

Another consequence of the need to make diagnostic and treatment decisions with limited information is that these decisions should be conservative. A 1-year study of diagnostic stability suggested that 38.7% of psychiatric emergency room patients received a different discharge diagnosis from the emergency room than they received from the inpatient service ([Woo et al. 2006](#)). Following the principles of Hippocrates, the emphasis is to make

treatment decisions in the best interests of the patient while balancing the need to prevent further harm. The ultimate goals are to provide adequate treatment of the underlying pathology based on a careful but succinct evaluation of the patient and to provide this treatment in the least restrictive environment while maintaining the safety of the patient, the clinician, and the staff.

As the numbers of psychiatric emergency cases continue to increase and flood general emergency rooms, new and novel methods of providing psychiatric consultation need to be explored. One method of expanding access to psychiatric services in emergency settings that has been underutilized in emergency psychiatry compared with other disciplines of medicine is telemedicine systems ([Hilty et al. 2013](#)). An essential requirement for developing these systems is a set of empirically derived and validated guidelines for implementation ([Shore et al. 2007](#)). There are qualitative data indicating that telemedicine systems might be useful in the diagnosis and management of psychiatric emergencies in emergency rooms without ready access to in-person psychiatric consultation ([Yellowlees et al. 2008](#)). These systems appear to be accepted by providers, staff, and patients ([Trondsen et al. 2014](#)).

Clearly, development of a well-trained work force of clinicians to deal with this rising tide of psychiatric emergencies is an urgent national imperative. The Accreditation Council for Graduate Medical Education (ACGME) does specify training requirements for emergency psychiatry for all psychiatric residents, which include a supervised experience in a 24-hour psychiatric emergency service, with direct clinical supervision from experienced attending physicians, and with no more than 50% of the experience allocated to off-hours call responsibilities. The

American Association of Emergency Psychiatry (AAEP) has proposed a curriculum and recommended training experience in response to the ACGME guidelines ([Brasch et al. 2004](#)). Disturbingly, a recent analysis of psychiatry training programs suggests that one-third do not adhere to the ACGME training guidelines for emergency psychiatry ([Bennett et al. 2011](#)). Efforts should be made through the American Association of Directors of Psychiatric Residency Training (AADPRT) and other organizations to ensure that all psychiatry residents receive adequate, high-quality training in psychiatric emergencies. But given that a large proportion of psychiatric emergency cases present to general emergency rooms, the case could be made that training in diagnosing and managing psychiatric emergencies should be provided to professionals other than psychiatrists, from physicians in emergency medicine residencies through nurses and other practitioners.

---

## Nonpharmacological Psychiatric Emergencies

---

Situations that require emergent psychiatric intervention but not psychopharmacological treatment include evaluation of need for hospitalization, assessment of suicide or homicide risk, determination of ability to care for self, and requirements to notify third parties to ensure safety of the patient or others ([Table 58-1](#)). Emergency psychiatrists are in a unique position of having to make predictions about patients' future behavior (e.g., suicide, homicide) and take appropriate preemptive action to prevent these outcomes. All states have civil commitment laws that allow for the

involuntary hospitalization of persons who by virtue of a mental illness may be considered an imminent risk to themselves or others. Typically, these laws allow for commitments of 48–72 hours in secure receiving facilities. Involuntary hospitalization beyond this holding period for observation and stabilization generally involves judicial review.

---

**TABLE 58-1. Psychiatric emergencies that do not require pharmacological intervention**

---

<b>Emergency</b>	<b>Intervention</b>
Suicidal state	Risk assessment Decision to admit
Homicidal state	Establish or rule out presence of psychiatric disorder Risk assessment Decision to admit <i>Tarasoff</i> notification
Grave disability, unable to care for self	Patient identification (if wandered from caregivers) Medical evaluation Decision to admit
Child, elder, spouse abuse	Notify/report to law enforcement and other agencies Referral to safe shelters

---

# Need for Hospitalization

The decision to hospitalize a psychiatric patient is dependent on several factors, but the welfare of the patient is of the greatest importance. There should be clear, definable treatment objectives for hospitalization, and the facility in which the patient is to be admitted should be capable of meeting those needs. Other factors that can contribute to the decision to hospitalize a patient include availability of psychiatric hospital beds and admission authorization by third-party payers ([Simon 1998](#)). Thus, the clinician must balance the availability of resources with the needs of individual patients.

Once the decision is made to hospitalize a patient, every effort should be made to have this occur on a voluntary basis. This is the first step in establishing therapeutic rapport with patients. The indiscriminate use of involuntary commitment can set up the perception of an adversarial relationship between patients and treatment providers ([Olofsson and Jacobsson 2001](#)). Avoiding experiences that elicit the perception of being “locked up” is one way of facilitating the long-term care engagement of the mentally ill patient.

## Suicidal State

Suicide is the tenth leading cause of death in the United States, with 41,149 suicide deaths in 2013, which translates into a population rate of around 13 deaths per 100,000 per year ([Centers for Disease Control and Prevention 2015](#)). One of the truly vexing problems in psychiatry is the lack of impact of specific psychiatric treatments on the suicide

rate. Several studies have failed to find any association between the availability of psychiatric treatment resources and the suicide rate ([Garlow et al. 2002](#); [Lewis et al. 1994](#)).

Predicting imminent suicide in any individual patient is difficult and can provoke significant anxiety in the clinician ([Pokorny 1983, 1993](#)). Suicide is a rare event, but it has profound effects on the surviving family members and friends of the patient and the physician and treatment staff ([Gitlin 1999](#); [Hendin et al. 2000](#)). There are also potential legal ramifications of a patient's suicide if he or she has been in recent contact with mental health providers ([Simon 2000](#)).

The relationship between suicidal ideation, attempted suicide, and completed suicide is complex ([Mościcki 1997](#)). No direct relation exists between any one of these states and the others. In one population-based study of completed suicides, 56% of the individuals died from the first attempt ([Isometsä and Lönnqvist 1998](#)). In another study of suicides, 75% of the individuals had no contact with mental health providers in the year prior to death ([Appleby et al. 1999](#)). One ominous finding was that 16% of the suicides occurred while the individuals were inpatients in psychiatric wards, and 24% occurred within 3 months after discharge from psychiatric facilities. In a 10-year follow-up study of patients admitted to the hospital for a medically serious suicide attempt, 25% made a second attempt, and 12% eventually died by suicide, with the majority of those deaths occurring in the 2 years following the index admission ([Isometsä and Lönnqvist 1998](#)).

Suicide risk is estimated by assessing both acute and chronic risk factors ([Table 58-2](#)), which include patient characteristics, nature of suicidal behavior, availability of a high-lethality means, and level of and access to psychosocial

support systems (e.g., family, friends, community) ([Hall et al. 1999](#); [Simon and Gutheil 2002](#)). This is an example of a psychiatric emergency in which acquiring reliable and accurate past and collateral history is essential, which may lead to some breach of patient confidentiality. Acute risk factors are most predictive of emergent suicidality and should carry the most weight in the decision to hospitalize a patient ([Busch et al. 2003](#)).

---

**TABLE 58-2. Acute and chronic risk factors for suicide**

---

<b>Acute</b>	<b>Chronic</b>
Increasing anxiety/frank panic attacks	Gender (male:female=4:1)
Psychic turmoil	Age (18-24 years; >65 years)
Global insomnia	Chronic illness
Mood-congruent nihilistic delusions	Race (white:nonwhite=2:1)
Profound hopelessness	Presence of a mental illness
Recent discharge from a psychiatric hospital	Substance abuse/dependence
Substance intoxication	Access to high-lethality means
Access to high-lethality means	Previous suicide attempts
Previous suicide attempts	Family history of suicide

---

Generating a comprehensive suicide risk assessment involves organizing and balancing risk with protective

factors. Clear documentation of these risk/protective factors, steps taken toward intervention, and associated clinical reasoning are essential. A basic statement describing competency should also be included. In the case of a chronically suicidal patient, clearly documenting this pattern and obtaining a second opinion to corroborate the treatment plan and objectives may be beneficial.

## **Acute Risk Factors**

Acute risk factors include increasing anxiety and frank panic attacks, psychic turmoil, global insomnia, mood-congruent nihilistic delusions, profound hopelessness, and recent discharge from a psychiatric hospital ([Busch et al. 2003](#); [Deisenhammer et al. 2007](#); [Fawcett 1992](#); [Fawcett et al. 1990](#)). Patients who are experiencing the first three of these symptoms should be viewed as being at particularly high risk regardless of whether they verbalize suicidal ideation.

Current intoxication is another acute risk factor. Recent alcohol consumption plays a role in 25%–50% of all suicides, and the consumption of both alcohol and cocaine may be particularly dangerous ([Cornelius et al. 1998](#)). Alcohol intoxication is related to higher rates of completed suicide, while cocaine intoxication is related to higher rates of suicidal ideation ([Garlow et al. 2002](#); [Garlow et al. 2003](#)). In this comprehensive series of individuals who died by suicide, 40% had alcohol or cocaine detected at the time of autopsy ([Garlow 2002](#)). Fully 21% of these individuals had blood alcohol levels above the legal limit for intoxication (0.08 µg/mL). Cocaine intoxication doubles the risk of suicide in white teenagers compared with African American teenagers ([Garlow et al. 2007](#)).

Previous suicide attempts are known precursors for completed suicide; thus, nonlethal suicide attempts are acute risk factors ([Deisenhammer et al. 2007](#); [Isometsä and Lönnqvist 1998](#); [Tejedor et al. 1999](#)). Consideration should be given to the actual lethality of the attempt; the patient's perception of that lethality; efforts made to conceal the attempt; calls for help; contacts with friends or family during the attempt; and use of a firearm. Access to firearms must always be determined in a suicide attempt and in someone who appears to be at high risk ([Conwell et al. 1996, 2002](#); [Miller et al. 2002](#); [Romero and Wintemute 2002](#)).

## **Chronic Risk Factors**

Chronic risk factors for suicide set the background on which acute risk is evaluated. They are derived from population-based analyses of suicides and often are not modifiable by any therapeutic intervention ([Kessler et al. 1999](#); [Mościcki 1997](#)). Males complete suicide four times more often than females, but females attempt suicide three times more often than males. Males tend to choose more lethal and violent means of suicide than females. Among males, firearms are the most commonly used (57.6%) method of suicide ([National Center for Injury Prevention and Control 2005](#)). Individuals age 65 years and older constitute 13% of the population but account for 19% of the suicides. The suicide rate for white men older than 85 years is 65 deaths per 100,000 population. A coincident risk factor is chronic illness, especially if diagnosed in the previous year. Another at-risk group is teenagers and young adults between the ages of 18 and 24 years, in whom suicide is the third leading cause of death.

Whites complete suicide two times more often than nonwhites, with white males accounting for 73% of the suicides in 1998 ([National Center for Injury Prevention and Control 2002](#)). The suicide rates for Native Americans are 1.5 times the national average. Suicide rates for specific ethnic groups change with the age and gender of the individual. In one study, African American males constituted the largest group, numerically and statistically, of teenage suicide victims but accounted for only 26% of victims from all age groups. In this same data set, African American females accounted for only 3% of all suicides, with only one occurring in an individual older than 45 years ([Garlow et al. 2005](#)).

Approximately 90%–95% of suicide victims have a major psychiatric illness, of which approximately half have a mood disorder ([Angst et al. 2002](#); [Fawcett 1992](#); [Harris and Barraclough 1997](#)). Male bipolar patients are at higher risk, especially those at an earlier phase of the illness, those who are currently in a depressed state, and those with comorbid substance abuse ([Simpson and Jamison 1999](#)). Patients with alcohol and other substance use disorders have higher rates of completed suicide than the national average, with alcoholic patients having a suicide rate twice the national average ([Fowler et al. 1986](#)). For alcoholic patients, comorbid depression and recent interpersonal loss increase risk ([Murphy and Wetzel 1990](#); [Murphy et al. 1992](#)). A family history of suicide increases suicide risk independent of a family history of mental illness ([Qin et al. 2002, 2003](#)).

Patients with borderline personality disorders often express ongoing suicidal ideation; as a result, suicidality becomes embedded in their sense of self ([Soloff et al. 1994](#)). This can manifest as repeated acts of self-injurious behavior, such as cutting and sublethal overdoses. These

patients can be very difficult to manage and can put a great deal of strain on the emergency medical and mental health delivery system. A consistently applied treatment plan, restrained responses on the part of clinical staff (minimizing countertransference behaviors), and use of secure 24-hour observation areas can be particularly useful in managing these patients. The goal is to allow patients to deescalate so that they can be discharged back into their ongoing outpatient treatment regimens ([Maltsberger and Buie 1974](#)).

## **Protective Factors**

In formulating a suicide risk assessment, it is important to note protective factors in addition to the presence or absence of acute and chronic risk factors. Protective factors against suicide include an expression of responsibility toward family, fear of social disapproval, moral objections to suicide, greater coping skills, and greater fear of suicide ([Malone et al. 2000](#)). Social connectivity also serves a protective role for depressed patients, as first described by Emile [Durkheim \(1951\)](#). Having close familial relationships, living with another person (family or friend), and having dependent children are all protective factors. Belonging to certain cultural groups, such as a community of faith, and having moral objections to suicide are associated with lower rates of suicide ([Dervic et al. 2004, 2006](#)).

## **Management of Suicidal Patients**

Ensuring safety is the first and most important step in managing a potentially suicidal patient. This can best be accomplished through admission to a secure patient observation area. If no such facility is available, close

observation by a trained staff member is another option. Staff assigned to monitor patients should be given specific instructions regarding their role and responsibilities.

The decision to hospitalize a potentially suicidal patient should take into account both acute and chronic risk factors; specific treatment needs of the patient; availability of other treatment options, including partial hospitalization, day treatment, and crisis group home settings; and social support network for the patient. Patients who are intoxicated and expressing suicidal ideation should be allowed to sober up before receiving a more definitive assessment. No-harm contracts between patients and clinicians are not useful in making treatment decisions with suicidal patients ([Kroll 2000](#); [Simon 1999](#)). Focusing on the acute behavioral state of the patient (anxiety, agitation, and insomnia), the presence of chronic risk factors, and access to high-lethality means (firearms) is much more relevant to making the decision to hospitalize the patient.

Patients who are not hospitalized require close follow-up, including a detailed treatment plan, an identified treatment provider, and instructions for the patient and family members on what to do in case of symptom worsening. Recommendations for management of acutely suicidal outpatients have been operationalized into an approach called Safety Planning Intervention (SPI). SPI is specifically designed to be deployed in emergency room settings for patients with suicidal ideation who are not hospitalized. A trained staff member assists the patient in developing a written document that includes warning signs, coping mechanisms, and sources of support and other treatment resources ([Stanley and Brown 2012](#)). Individuals with access to high-lethality means should be advised to remove these items from the home. Firearms and medications

lethal in overdose should be neither in the home nor readily accessible. Family members and friends may be consulted to assist with the removal of these items from the patient's possession ([Mann et al. 2005](#)).

Another approach being investigated for the management of suicide risk in patients is the use of cognitive-behavioral therapy (CBT) ([Brown and Jager-Hyman 2014](#)). In one seminal report on the use of CBT with suicidal patients initially assessed in a general emergency room, patients who received a 10-session CBT intervention were much less likely to make a second suicide attempt within the 18-month follow-up period compared with those who did not receive this intervention ([Brown et al. 2005](#)). The patients who received CBT also had improvements in depression symptom severity and lower levels of hopelessness than those in the control group.

Although management of emergent suicide risk has historically not been considered to warrant acute pharmacological interventions, recent evidence suggests that the dissociative anesthetic agent ketamine may have specific therapeutic benefit in suicidal patients ([Price and Mathew 2015](#)). Single and repeated infusions of subanesthetic dosages of ketamine (0.5 mg/kg body weight) have been shown to rapidly relieve symptoms of depression and suicidal ideation ([DiazGranados et al. 2010](#); [Price et al. 2009](#)). The antisuicide response appears to occur regardless of the impact on severity of mood symptoms, suggesting a specific antisuicide action of ketamine ([Ballard et al. 2014](#)). Pilot investigations of ketamine infusions in acutely suicidal patients in emergency room settings provide tantalizing preliminary evidence that this intervention may offer a novel method of managing acute suicide risk ([Larkin and Beautrais 2011](#)). Clearly, additional

research is needed to fully determine the utility, if any, of this intervention in general clinical practice.

## Homicidal State

Establishment of a psychiatric diagnosis is the first step in developing a management plan for a patient expressing homicidal ideation. Whereas suicide most often occurs in the context of a mental illness, homicide and homicidal behaviors do not. There is a relation between sadness and other negative affective states and suicide, but there is no correlation between these mood states and homicidal or violent acts ([Apter et al. 1991](#)). Nonetheless, a patient may develop homicidal ideation in the context of a psychotic disorder, particularly disorders that include firmly held paranoid, persecutory, or erotomanic delusions. If such delusional beliefs are driving the expression of homicidal ideation, involuntary hospitalization would be the appropriate course of action.

Expressions of anger, hostility, rage, and violent intent occur in many interpersonal situations and conflicts in which the perpetrator does not have a psychiatric disorder. In these cases, once a determination has been made that the individual is not psychotic or delusional or expressing homicidal ideation on the basis of some other psychiatric disorder, appropriate interventions are in the domain of law enforcement, not psychiatry.

If a patient who is expressing homicidal ideation is not admitted to a psychiatric facility, the clinician must give very careful consideration to the need to notify the intended victim and law enforcement agencies based on the principles set forth in *Tarasoff v. Regents of the University*

of California ([Tarasoff 1976](#); [Simon 1998](#); [Walcott et al. 2001](#)). This case established a precedent for mental health workers to breach confidentiality to notify an intended victim and law enforcement agencies if they are aware of a patient's plan to harm that victim. Adoption of the principles set forth in the *Tarasoff* ruling varies by state.

Predicting which individuals may act on homicidal ideation is very difficult ([Resnick and Scott 2000](#)). Factors that contribute to this assessment are the specificity of the plan, identity of the victim, access to high-lethality means (firearms), capacity of the patient to persist in the plan, and proximity of the perpetrator to the intended victim ([Borum and Reddy 2001](#)). Even with a careful history, assessment, and appropriate intervention, preventing an adverse outcome may not be possible. In the *Tarasoff* case, the police determined that the perpetrator was not a threat when they interviewed him, but he eventually carried out the lethal act 3 months later.

## Grave Disability and Inability to Care for Self

Another condition for which involuntary commitment laws exist is when patients by virtue of a mental illness are unable to care for themselves; some states also include "as a result of substance abuse disorders" under this heading (K.T. [Hall and Appelbaum 2002](#)). The consideration is whether the patient cannot provide adequately for basic needs, shelter, food, and medical attention because of a mental illness. A common example of this situation is a patient with a psychotic disorder who is living on the streets, without regular or adequate nutrition, and

neglecting his or her ongoing medical conditions. This situation is not the same as that in which a person is homeless because of some other occurrence or circumstance, because homelessness does not in itself constitute grave disability. Another common situation that falls under this heading is a patient with dementia or other profound cognitive impairments who has wandered away from his or her caregivers. In this case, effort should be focused on establishing the identity of the individual and returning him or her to the appropriate facility.

## Notification of Third Parties

The principles set forth by the *Tarasoff* ruling in California encourage clinicians to act in the best interests of the intended victim, with notification of the intended victim and law enforcement agencies in the case of expressed homicidal ideation. This places a unique burden on psychiatrists—to predict future behavior of a patient and to assume responsibility for the welfare of another person with whom the psychiatrist does not have a therapeutic relationship.

Another circumstance that requires breach of patient confidentiality is notification of authorities in cases of suspected child abuse and neglect. All states have statutes that require clinicians of all disciplines to notify the appropriate agency in the case of suspected child abuse. Many states also have laws for reporting elder abuse and abuse of other vulnerable individuals.

---

# Psychiatric Emergencies Requiring Minimal or Adjunctive Pharmacological Intervention

---

Psychiatric emergencies requiring minimal or adjunctive pharmacological intervention occur in many different situations, although many share a common thread of developing in response to some discrete, identifiable stressor (Table 58-3). The practice of crisis intervention psychiatry involves identifying the root cause or stressor of the presenting syndrome and developing a focused treatment plan. The principal therapeutic goals are to alleviate short-term distress, rapidly return the patient to his or her previous level of functioning, and prevent the development of a more serious long-term syndrome. The judicious use of psychopharmacological agents, in concert with psychotherapeutic, psychosocial, and family system interventions, can be particularly effective in these emergencies.

Panic disorder	Medical evaluation Short course of benzodiazepine Treatment referral

## Adjustment Disorders

Adjustment disorders are defined as the maladaptive response to an identifiable psychosocial stressor within 3 months of onset of the stressor, with the symptoms having persisted for no more than 6 months after termination of the stressor ([American Psychiatric Association 2013](#)). The common clinical manifestations of adjustment disorders encountered in psychiatric emergency settings involve a mixture of anxiety, depressive, and neurovegetative symptoms in response to some external stressor or crisis. The potential stressors are myriad, including death of a family member or friend, job loss, diagnosis of a serious medical condition, divorce and other disturbances of family function, financial hardship, and many other circumstances.

The principal interventions for adjustment disorders are psychotherapeutic, educational, and psychosocial. Most crises have a natural time course and resolution. Feelings of distress in response to many of these insults are innate and expected. Psychoeducational interventions are aimed at

helping the patient realize that the syndrome is self-limited and expectable in response to the stressor. Often, these patients have a sleep disturbance, so the short-term use of a soporific (diphenhydramine 25–50 mg, hydroxyzine 25 mg, trazodone 50–100 mg, mirtazapine 7.5–15.0 mg) or a sedative-hypnotic (zolpidem 5–10 mg, zaleplon 5–10 mg, eszopiclone 2–3 mg, ramelteon 8 mg) could be considered to assist in reestablishing a normal sleep-wake cycle. In general, benzodiazepine use should be avoided, because there is no evidence that the early use of these agents prevents the eventual development of more serious disorders such as posttraumatic stress disorder (PTSD) ([Gelpin et al. 1996](#)).

## Acute Trauma

Patients who have been exposed to a catastrophic stressor or an acute psychological trauma are at risk for developing acute stress disorder (ASD) or PTSD ([Foa et al. 1989](#)). The definition of a traumatic event includes direct personal experience of an event that involves actual or threatened death, injury, or threat to one's physical integrity or witnessing such an event or learning about such an event happening to a family member or close associate. Most people who experience such traumas do not go on to develop any psychiatric disorder, but a significant minority, up to 30%, will develop PTSD.

Psychological debriefing has become one of the standard interventions after traumatic events ([Mitchell 1983](#)). A trained moderator conducts the debriefing with the goal of encouraging the expression of thoughts and feelings about an event shortly after it has occurred. This type of

intervention is commonly offered to both the victims of a trauma and the care providers (e.g., police officers, firefighters, emergency medical technicians) that were involved. Evidence shows that the timing of the debriefing is critical and that this might not be the ideal posttraumatic intervention in all situations ([Campfield and Hills 2001](#); [Greenberg 2001](#)). An evolving approach to immediate trauma intervention is to assess the risk of a patient developing PTSD and educate the patient about normal reactions to trauma and potential symptoms of PTSD. Other studies have evaluated the use of brief CBT for patients with acute traumatic exposures. One such study indicated accelerated rates of recovery in patients who received this intervention ([Sijbrandij et al. 2007](#)).

Behavioral indicators of risk of developing PTSD include heightened levels of arousal and coping via disengagement after a traumatic event ([Mellman et al. 2001](#)). Personalization of the traumatic event, especially thoughts that one might die, is another risk factor. The typical time course for posttraumatic reactions to resolve is on the order of 4 weeks. During this time, it is extremely common for all trauma victims to experience some of the symptoms of PTSD. One of the main early therapeutic goals should be to educate patients about this time course and to encourage them to return to treatment if these symptoms persist past 4 weeks or become particularly debilitating. Referral to trauma-specific psychotherapies (rape crisis, violent crime, survivor groups) can be helpful to victims of these specific insults.

The use of benzodiazepines is controversial in the context of acute trauma. While these medications may be useful in decreasing overall levels of anxiety, there is no clinical evidence supporting their use as prophylaxis against the

development of PTSD. The Consensus Statement on PTSD from the International Consensus Group on Depression and Anxiety discouraged the use of benzodiazepines secondary to limited efficacy, concern for tolerance and withdrawal, and the possibility of “impairment of learning” ([Ballenger et al. 2000, 2004](#)). If the decision is made to use these medications, long-half-life agents, such as clonazepam and diazepam, minimize the risk of withdrawal or rebound anxiety ([Davidson 2004](#)).

## Conditions That Require Medical Evaluation

With any acute change in mental status or sudden-onset change in behavior in a previously well individual, organic causes must be considered first, before it is assumed that the symptoms are a manifestation of a previously undiagnosed psychiatric disorder ([Frame and Kercher 1991](#); [Hall et al. 1978, 1981](#)). This is especially true when the syndrome occurs outside of the usual age-based window of vulnerability. For example, new-onset psychotic symptoms in a patient older than 40 years or mania in a patient older than 50 years should be considered to be due to a medical condition until proven otherwise.

### **Panic Disorder**

A patient presenting for the very first time with dyspnea, tachycardia, diaphoresis, chest pain, and light-headedness should receive a thorough medical evaluation before being assigned a diagnosis of panic disorder. Many different conditions can present with some or all of these symptoms,

including unstable angina and myocardial infarction, hypoglycemia, anemia, pulmonary embolism, asthma, obstructive pulmonary disease, gastroesophageal reflux disease, irritable bowel disease, hyperparathyroidism, hyperthyroidism, pheochromocytoma, Huntington's disease, Parkinson's disease, seizure disorder, and auto-immune disorders, such as systemic lupus erythematosus ([Roy-Byrne et al. 2006](#)). Only after these medical conditions have been ruled out should a diagnosis of panic disorder be entertained. Current U.S. Food and Drug Administration (FDA)-approved medications for panic disorder include alprazolam (a benzodiazepine), sertraline and paroxetine (selective serotonin reuptake inhibitors [SSRIs]), and venlafaxine (a serotonin-norepinephrine reuptake inhibitor). SSRIs tend to be utilized first line because of their general tolerability, lack of potential for dependence/misuse, and good safety profile ([Katon 2006](#)).

## **Dissociative Episodes**

Amnestic and acute confusional states should always be considered to be due to a medical or neurological condition until proven otherwise. Amnestic symptoms are common after head injury, during cerebrovascular accidents and transient ischemic accidents, in postictal states, with brain tumors, in intentional and unintentional intoxications, and in many other medical conditions. Another important diagnostic consideration is of a delirium, which could have any number of medical or metabolic causes. Establishing the correct diagnosis in this type of patient is facilitated by extended observation, with repeated assessments. This allows for detection of the fluctuating levels of consciousness and awareness common in delirium and of the temporal evolution of the amnestic symptoms.

Unobtrusive observation of these patients also allows for assessment of purposeful, deliberate, and organized behaviors, which are observed in patients with psychogenic or factitious amnestic conditions but often are not seen in those with an organic condition.

## **Catatonia**

Catatonia is a syndrome characterized by the presence of at least three of the following symptoms: stupor, catalepsy, waxy flexibility, mutism, negativism, posturing, mannerisms, stereotypy, agitation, grimacing, echolalia, and echopraxia ([Fink and Taylor 2006](#); [Taylor and Fink 2003](#)). Catatonia can occur in psychiatric and nonpsychiatric conditions and can be diagnosed in 7%–15% of psychiatric patients in acute inpatient services and emergency room settings ([Fink and Taylor 2006](#)). If a patient has not had previous documented episodes of catatonia in conjunction with a known psychiatric disorder, a medical cause should be sought vigorously. Episodes of catatonic behavior can occur in a variety of neurological and medical conditions, including metabolic encephalopathies, viral encephalitis, cerebrovascular accidents, epileptic episodes, hypercalcemia, and adverse medication (e.g., antipsychotic) or drug (e.g., phencyclidine [PCP]) side effects. These conditions should be ruled out before a psychiatric diagnosis is made. Although no established standard of care exists for the treatment of catatonia, acceptable treatment options include intravenous barbiturates (e.g., amobarbital) and benzodiazepines (e.g., lorazepam), as well as electroconvulsive therapy (ECT) ([Fink 2001](#); [Rosebush et al. 1990](#)).

## **Mania or Psychosis**

New-onset mania or psychosis should always be approached as being potentially caused by a medical condition. The clinical context will guide the urgency of the medical evaluation. New-onset psychotic symptoms in a 40-year-old and new-onset mania in a 50-year-old should prompt an urgent medical evaluation. Such symptoms appearing in an adolescent or a young adult should still be evaluated medically, although not with the same urgency as in the older adult. These symptoms can be caused by brain tumors, cerebrovascular accidents, autoimmune disorders, multiple sclerosis, and hyperthyroidism. Many medications, including exogenously administered steroids and stimulants, as well as illicit drugs can provoke manic and psychotic symptoms. Therefore, a thorough physical examination and a urine drug screen are essential components of the diagnostic workup.

## **Conversion Disorder (Functional Neurological Symptom Disorder)**

Conversion disorder is a diagnosis of exclusion. Accordingly, new-onset neurological symptoms, including non-epileptic seizures, non-anatomical movement disorders, paresthesias, paresis, and amnestic syndromes, should be thoroughly evaluated before being attributed to a psychogenic cause. Management of conversion symptoms includes a complete medical assessment and reassurance that the symptoms will resolve with time. Long-term management involves both physical rehabilitation and treatment of the underlying psychological conflict or distress. Family therapy can be a useful tool, given that family dynamics are often an essential part of the psychosomatic response to stress ([Hurwitz 2004](#)).

---

# Psychiatric Emergencies That Usually Require Pharmacological Intervention

---

Management of severe behavioral emergencies usually requires psychopharmacological intervention prior to definitive diagnosis (Table 58-4). Many psychiatric patients will have episodes of disorganized, disinhibited, agitated, aggressive, or violent behavior. These behavioral states can occur in patients who are psychotic, manic, or intoxicated as well as in those who have organic syndromes such as traumatic brain injury, dementia, or delirium. Patients who are experiencing severe medication side effects also require pharmacological intervention, as do patients with substance use disorders in withdrawal states.

---

**TABLE 58-4. Psychiatric emergencies that usually require pharmacological intervention**

Lorazepam

Haloperidol

Atypical (second generation) antipsychotics

Definitive diagnosis and treatment plan

Delirium

Diagnose delirium vs. other disorder

Definitive medical diagnosis

Treat underlying cause

Intravenous (IV) or intramuscular (IM) haloperidol

Ethanol or sedative-hypnotic withdrawal

Benzodiazepine to stabilize withdrawal symptoms

Controlled taper under supervision

Referral to chemical dependency treatment

Alcohol withdrawal delirium

Medical intensive care

Supportive measures

Benzodiazepine taper

## Medication side effects

Emergency	Intervention
Antipsychotic-induced dystonia	Acute: Diphenhydramine 25–50 mg IV Maintenance: Diphenhydramine 25–100 mg once daily (QD), or Benztropine 0.5–4.0 mg QD, or Trihexyphenidyl 2–10 mg QD
Antipsychotic-induced akathisia	Reduce antipsychotic dose Propranolol 10 mg two to three times daily Benzodiazepine
Neuroleptic malignant syndrome	Discontinue offending agent Medical intensive care/support: Cooling Hydration Anticoagulation Dantrolene Benzodiazepine Electroconvulsive therapy
Anticholinergic delirium	Discontinue offending agent(s) Supportive measures

<b>Emergency</b>		<b>Intervention</b>
Hypertensive crisis		Management of blood pressure
Serotonin syndrome		Supportive measures Discontinue offending agent Medical supportive measures/intensive care Benzodiazepine
Priapism		Discontinue offending agent Medical supportive measures Urology evaluation if condition does not resolve
Selective reuptake discontinuation syndrome	serotonin inhibitor	Reassurance; restart medications

## Assaultive, Aggressive, or Violent Behavior

Assaultive, aggressive, and violent behaviors can have many different etiologies, including psychotic or delusional ideation secondary to a primary psychotic or mood disorder, intoxication, acute confusional states associated with dementia and delirium, rage attacks in patients with

personality disorders, and deliberate, volitional acts by antisocial individuals. The most important chronic risk factor for predicting violent behavior is a history of such behavior. Acute risk factors include over- or undercontrolled behavior. The former refers to a patient with decreased psychomotor activity, tension, anger, and paranoia, whereas the latter refers to a patient who is agitated, intrusive, and verbally provocative. Intoxication is an independent acute risk factor that can potentiate violent behaviors in patients with many different diagnoses.

A well-trained staff of an adequate number in an appropriately designed facility is the best strategy for preventing violent episodes. Staff members who are trained to respond in a calm, deliberate, and nonthreatening manner help to establish an atmosphere of order and control. Preventing a violent act from occurring is preferable to responding to a violent act after it has occurred. It is better to have a patient take a medication voluntarily and orally before his or her behavior has escalated than to be required to involuntarily medicate the patient after a crisis has occurred. Research has suggested that clinicians may overutilize intramuscular injections because they are easy to administer ([Damsa et al. 2006](#)).

There are several pharmacological options in the acute management of the agitated patient. Orally available agents include benzodiazepines and antipsychotics. Lorazepam in 2-mg doses given every 45–60 minutes will sedate most patients by the second dose. Other alternatives are 15–20 mg of olanzapine, 4–6 mg of risperidone, or 5 mg of haloperidol in a single oral dose. If a patient with a known diagnosis of schizophrenia or bipolar disorder is experiencing a psychotic or manic decompensation, a second-generation (atypical) antipsychotic should be used.

If the diagnosis is not known or is unclear, then lorazepam is a better choice, especially in view of the fact that acute intoxication with some agents—for example, anticholinergics such as diphenhydramine—may be worsened by the addition of second-generation antipsychotics.

New alternatives to the established pill or tablet formulations of second-generation antipsychotics are available and have demonstrated positive results in comparative trials. Risperidone M-Tab, Zyprexa Zydis, and Abilify Discmelt are rapidly dissolving forms of their parent agents. Risperidone is also available in an oral concentrate solution. These formulations exhibit benefit over the traditional pill formulation for patients who “cheek” medications (i.e., store the administered pill in their cheeks and subsequently dispose of it rather than swallowing it) ([Allen et al. 2001, 2005](#)). The FDA recently approved an inhaled form (marketed under the name Adasuve) of loxapine, a first-generation antipsychotic with second-generation properties ([Alexza Pharmaceuticals, Inc. 2016](#)). This route of administration may have a more rapid onset of action than other formulations; however, the overall clinical utility and safety of this agent have yet to be determined.

Involuntary administration of psychotropic medications is permitted in behavioral emergencies, although rather wide variations exist in the legal definitions and rules regarding the practice of administering involuntary medication. Clinicians should be well informed about the local definitions and regulations regarding involuntary administration of psychotropic medication. Accurate and timely documentation of the need for restraint and involuntary medication administration is essential.

Currently, six medications are suitable for intravenous or intramuscular administration in behavioral emergencies: the benzodiazepines lorazepam and diazepam; the first-generation antipsychotic haloperidol; and the second-generation antipsychotics olanzapine, ziprasidone, and aripiprazole. Lorazepam is the most useful and should be the mainstay for controlling behavioral emergencies ([Battaglia et al. 1997](#); [Foster et al. 1997](#); [Salzman et al. 1991](#)). Lorazepam is rapidly absorbed from intramuscular injections, has a rapid onset of action and a short half-life, and is anxiolytic as well as sedating. Patients who are being combative generally are experiencing high levels of fear or anxiety, so the anxiolytic properties of lorazepam are an additional advantage. Absorption of intramuscular diazepam can be erratic; therefore, this medication is not particularly useful. Haloperidol should be reserved for patients who are clearly psychotic, with the expectation that they will be receiving long-term treatment with an antipsychotic agent.

In a behavioral emergency, a sufficiently large dose should be given with the first injection to ensure rapid onset of sedation and to minimize the need for a second or third injection. Lorazepam should be administered in 2-mg doses that can be repeated at 45 minutes if the initial dose is not sufficient. Very rarely will any additional injections be required after a second 2-mg dose of lorazepam. The initial haloperidol injection should be 2.5–5.0 mg and should not be repeated for at least 2 hours. Sufficient time must be given for the medication to be absorbed and for maximal sedation to occur. Under no circumstances should a patient receive more than 5 mg of haloperidol in a single injection or more than two injections (10 mg) in 24 hours, which can provoke a severe dystonic reaction. To prevent dystonia, 1

mg of benztropine should be included with intramuscular haloperidol. Alternatively, 25 mg of diphenhydramine may be added to prevent dystonia while providing additional sedation. The combination of lorazepam and haloperidol in a ratio of 2 mg of lorazepam to 5 mg of haloperidol is often used to provide adequate sedation and anxiolysis while treating the underlying psychosis.

The injectable second-generation antipsychotics should be reserved for patients who will be given an oral second-generation agent after the immediate emergency has resolved. Intramuscular ziprasidone has been studied in patients with schizophrenia who were psychotic and agitated and is currently indicated for the treatment of these conditions ([Daniel et al. 2001](#); [Lesem et al. 2001](#)). In these clinical trials, patients received an initial injection of 10 mg, followed by injections of 5–20 mg every 4–6 hours, for a maximum dose of 80 mg in 24 hours. The package insert for intramuscular ziprasidone ([Pfizer, Inc. 2015](#)) recommends doses of 10–20 mg, with 10-mg doses repeatable at 2-hour intervals or 20-mg doses at 4-hour intervals. The maximum recommended intramuscular dose in 24 hours is 40 mg. Intramuscular ziprasidone appears to have a low incidence of extrapyramidal side effects compared with intramuscular haloperidol ([Brook et al. 2000](#)). Results from one naturalistic study suggest that the use of intramuscular ziprasidone may reduce time in restraints for agitated patients compared with treatment with a first-generation agent ([Preval et al. 2005](#)).

Injectable olanzapine has been studied for use in agitated patients with schizophrenia, bipolar mania, or dementia ([Breier et al. 2002](#); [Meehan et al. 2001, 2002](#); [Wright et al. 2001](#)). In the schizophrenia trials, patients received up to three individual injections of 2.5–10.0 mg in 24 hours, with

the higher doses producing more significant and sustained reduction of agitation. In the bipolar trials, patients received up to three injections of 5 or 10 mg of olanzapine in 24 hours, with significant reduction in agitated behaviors. In the dementia trial, agitated patients received up to three olanzapine injections of 2.5 or 5 mg in 24 hours, with significant reduction in agitation. A review of the literature by [Tulloch and Zed \(2004\)](#) concluded that injectable olanzapine was superior to placebo in all study populations and to intramuscular lorazepam in patients with bipolar disorder. However, this review further concluded that injectable olanzapine did not differ significantly from intramuscular haloperidol or lorazepam in the management of agitation associated with schizophrenia/schizoaffective disorder or dementia. It is relevant to note that olanzapine is FDA approved for the treatment of schizophrenia and bipolar mania, but not for management of agitation associated with dementia.

Injectable aripiprazole is approved for the treatment of agitation in patients with schizophrenia and bipolar mania. Efficacy studies found that injectable aripiprazole at a dose of 9.75 mg was superior to placebo and comparable to injectable olanzapine. Injectable aripiprazole demonstrated tolerability and symptom reduction without oversedation ([Tran-Johnson et al. 2007](#)).

## Schizophrenia

Atypical (second-generation) antipsychotics represent the current standard of care for the treatment of acute agitation in patients with schizophrenia ([American Psychiatric Association 2004](#)). With proven efficacy and improved tolerability in comparison with haloperidol, these agents represent the first-line treatment in the agitated

psychotic patient ([Aleman and Kahn 2001](#); [Currier and Trenton 2002](#); [Yildiz et al. 2003](#)). The optimal intervention in a patient with schizophrenia who is experiencing an acute exacerbation is to rapidly initiate treatment with a second-generation antipsychotic. In this regard, risperidone and olanzapine are the most useful agents, because both can be initiated at a high therapeutic dose (15–20 mg for olanzapine; 4–6 mg for risperidone) and can be given in multiple oral doses (two or three doses) over a period of 24 hours.

In a patient who is too disorganized or combative to take medication orally, intramuscular administration is the only viable route. Currently, chlorpromazine, haloperidol, ziprasidone, olanzapine, and aripiprazole are available in injectable preparations. In a patient who is psychotic and agitated, coadministration of a benzodiazepine during the first few days of treatment can be particularly effective in controlling behavior while the antipsychotic response develops. Studies suggest that this combination may reduce the total antipsychotic dosage required and potentially result in fewer adverse antipsychotic effects ([Salzman et al. 1991](#); [Yildiz et al. 2003](#)). One caveat to this choice of treatment is the increased risk of sedation and cardiorespiratory depression associated with the combined use of intramuscular olanzapine and intramuscular lorazepam, which led to a black box warning in the prescribing information provided by Eli Lilly, the manufacturer of olanzapine ([Lilly USA 2017](#)).

## **Bipolar Disorder**

The goal of managing acutely manic patients is to rapidly establish a long-term definitive treatment regimen, which means initiating a mood-stabilizing agent such as lithium

(10–20 mg/kg) or valproic acid (20–30 mg/kg) as soon as possible. Prior to initiating either of these two agents, a serum pregnancy test should be obtained and documented as negative, since both agents are teratogenic. Both lithium and valproic acid require time to reach a therapeutic blood level and may take up to 14 days to become fully effective. Until steady state is established, behavioral control can be achieved with oral or intramuscular lorazepam on an as-needed basis or with a second-generation antipsychotic such as olanzapine, risperidone, ziprasidone, quetiapine, or aripiprazole, all of which are FDA approved for the treatment of acute bipolar mania. Olanzapine, risperidone, and quetiapine have the advantage of being sedating, which can be useful in an emergency room setting. A review of the literature indicated that intramuscular olanzapine was superior to lorazepam monotherapy in the treatment of agitated manic patients ([Tulloch and Zed 2004](#)). If the long-term plans do not include an antipsychotic, lorazepam or another benzodiazepine should be used for short-term behavioral control. If, however, the plan is to use both a mood stabilizer and an antipsychotic for long-term management, an antipsychotic should be substituted for the benzodiazepine.

## **Substance Intoxication**

Violent and combative behavior by intoxicated patients is a very common occurrence in psychiatric and medical emergency departments. Alcohol, cocaine, PCP, methamphetamines,  $\gamma$ -hydroxybutyrate (GHB), and hallucinogens and “designer” drugs (modified cathinones such as bath salts and Flakka) can lead to violent behavior. Recent research in a large urban psychiatric emergency room suggests that use of designer drugs may be a larger

problem than was previously appreciated. In this analysis, standard urine drug screening systems missed a significant number of cases of drug ingestion. Use of a more sensitive enzyme-linked immunosorbent assay (ELISA) and gas chromatography-mass spectrometry (GC-MS) system identified patients who had ingested opiates and amphetamines that were not detected by the standard screening test. This more sensitive detection system also identified a number of patients who had used designer drugs such as cathinone derivatives and tryptamines, which are not detectable with standard screening systems ([Reidy et al. 2014](#)).

Ethanol intoxication is a very common cause of violent behavior. The appropriate interventions are physical restraint and sedation with a benzodiazepine or haloperidol if the agitation is significant, to allow the patient to become sober. Once a patient's blood alcohol level is below the legal limit for intoxication, a more definitive evaluation can be carried out, focusing on presence of an underlying psychiatric diagnosis or other treatment needs.

Prolonged cocaine use can lead to development of both mood and psychotic syndromes. Transient paranoid states are very common in cocaine users, as are frank delusions and hallucinations. Agitated, paranoid states accompanying cocaine intoxication can lead to significant violent behavior. Interventions include seclusion and restraint, use of intramuscular lorazepam, and use of an antipsychotic if the patient is frankly psychotic. When the patient is no longer intoxicated, the presence of underlying psychopathology can be assessed.

PCP intoxication can be particularly provocative of agitated, combative, and violent behavior. Fortunately (or unfortunately), PCP use tends to occur in localized

geographical regions. In areas where PCP use is common, intoxicated persons are common in emergency facilities. PCP intoxication can present with frank psychotic symptoms, agitation, disorientation, and disorganized behavior. Violent outbursts can be sudden, unprovoked, and unexpected. Patients in the throes of PCP intoxication can be very insensitive to pain, so they are prone to continue to fight even if seriously injured. Adequate numbers of well-trained staff are essential when dealing with patients who have been using PCP. Restraint rooms should be dark and quiet so as to minimize stimulation. Intramuscular lorazepam should be used to sedate the patient. The half-life of PCP is 20 hours, so these behavioral states can persist for several days before fully resolving.

Methamphetamine; designer drugs such as bath salts and Flakka, which are amphetamine-like; and GHB can cause agitated, disorganized, and violent behavior. Methamphetamine in particular can have behavioral consequences very similar to those of cocaine. Because of the long half-life of methamphetamine compared with cocaine, this drug can be particularly provocative of frank paranoid and psychotic symptoms. There have been significant increases in cases of intoxication with designer drugs such as bath salts and Flakka in some localities. These patients can have psychotic, paranoid, agitated, and violent presentations.

Presenting symptoms of methamphetamine intoxication often include agitation, hallucinations, suicidal ideation, and chest pain ([Derlet et al. 1989](#)). Distinguishing stimulant intoxication from other clinical conditions can be challenging, given the symptom overlap. Generally, stimulant-induced psychosis tends to be distinguishable from primary psychotic disorders by the absence of a

thought disorder and a prominence of visual hallucinations ([Harris and Batki 2000](#)). However, given the potential for comorbidity, a positive drug screen does not completely discount the diagnosis of a mood or psychotic disorder. Treatment should focus on maintaining the patient's safety while awaiting the drug's metabolism and dissipation from the patient's system.

## **Delirium**

Patients with delirium can become disorganized, agitated, and combative. Delirium is defined as a state of disturbance in attention, awareness, and cognition, during which the symptoms occur rapidly and fluctuate with time. Delirium may be due to a general medical condition or to substance intoxication or withdrawal; it may also be secondary to multiple etiologies ([American Psychiatric Association 2013](#)). Delirium is a medical emergency and carries a very high burden of morbidity and mortality. The definitive treatment of delirium requires diagnosing the underlying cause and taking corrective action. Interventions aimed at controlling behavior include restraints, environmental modification including frequent reorientation of the patient, and use of intravenous haloperidol. Behavioral control is essential so that the patient does not further injure him- or herself or interfere with treatment and to protect staff and other patients. The first intravenous dose of haloperidol should be 2.5 mg. If the patient is still agitated after 2 hours, the dose should be increased to 5 mg. This dose can be repeated in another 2 hours if the patient continues to be agitated. Once the patient is stabilized, a routine antipsychotic regimen should be initiated, dividing the total dose into two or four regular doses. The antipsychotic can be decreased

and discontinued as the delirium clears. Benzodiazepines are generally contraindicated in cases of delirium.

## **Dementia**

Patients with dementia can become agitated, combative, or psychotic for many different reasons. The most common cause for these symptoms is a delirium superimposed on the dementia. Definitive diagnosis and treatment of the disorder causing the delirium are essential to achieving adequate long-term resolution. Patients with dementia who are not delirious can become agitated as a result of confusion or psychosis inherent in the neurodegenerative pathology. In these cases, the best interventions are nonpharmacological and include environmental modification, behavior modification, and supportive measures. Aggressive behavior in patients with dementia can be treated pharmacologically, in the short term with low-dose antipsychotics and in the long term with low-dose antipsychotics, the anticonvulsants carbamazepine or valproic acid, the  $\beta$ -blocker propranolol, the SSRI antidepressants, or the anxiolytic drug buspirone. As is true in all geriatric prescribing, low doses and slow titration schedules are the appropriate course. Second-generation antipsychotics are not approved for the treatment of dementia-related psychosis, and the prescribing information carries a black box warning regarding an increased risk of death from cerebrovascular events (e.g., sudden cardiac arrest) and infections (e.g., pneumonia) in elderly patients who are treated with these agents ([Schneider et al. 2005](#)).

## **Substance Withdrawal States**

## Alcohol and Sedative-Hypnotics

Alcohol or sedative-hypnotic withdrawal can result in a frank delirium that is life-threatening ([Marco and Kelen 1990](#); [Olmedo and Hoffman 2000](#)). The acute signs of early alcohol, sedative-hypnotic, and benzodiazepine withdrawal are similar and include autonomic instability, tremulousness, diaphoresis, and gastrointestinal disturbances. Autonomic signs include tachycardia, hypertension, and hyperthermia. Treatment of this withdrawal state is best accomplished with symptom-triggered (vital signs and/or Clinical Institute Withdrawal Assessment [CIWA] scores) administration of a long-half-life benzodiazepine. Use of long-half-life agents such as diazepam or chlordiazepoxide prevents peaks and troughs in blood levels. During the first 72 hours, vital signs and/or CIWA scores should be obtained at 2- to 4-hour intervals and additional benzodiazepine given if vital signs are still elevated. This approach has been shown to reduce total time and medication exposure in the detoxification phase. It is important to consider concomitant medications, given that  $\beta$ -blockers prescribed for a general medical condition may mask the autonomic signs of withdrawal.

Alcohol withdrawal delirium (delirium tremens) is a life-threatening medical condition ([Erwin et al. 1998](#)). This syndrome has a very high mortality rate—up to 35% in untreated patients and as high as 5%-15% in optimally treated patients. The delirium usually develops 48-72 hours after discontinuation of alcohol or sedative-hypnotics, peaks around day 4, and can persist for weeks. The symptoms include autonomic instability, fever, disorientation, perceptual disturbances and hallucinations, agitation, and confusion. Patients with delirium tremens should be treated

in a medical intensive care unit. These patients typically require physical restraint and vigorous supportive measures. Intravenous haloperidol can be used to control agitation and psychosis. High doses of benzodiazepines have also been used in this situation to manage agitated behavior.

Wernicke-Korsakoff syndrome is another consequence of long-term alcohol use. Wernicke encephalopathy is the symptom complex of ophthalmoplegia, ataxia, and an acute confusional state. Wernicke-Korsakoff syndrome is diagnosed if persistent learning and memory deficits are also present. Alcoholic patients should receive three daily 100-mg doses of thiamine via the intramuscular route from the day of presentation, followed by three daily oral doses to prevent development of this syndrome. Patients should receive the first intramuscular dose before oral or intravenous administration of a carbohydrate load in order to prevent rapid thiamine depletion and emergent development of Wernicke-Korsakoff syndrome. Patients should also be given folic acid and magnesium replacement supplementation.

## **Opiates**

Opiate withdrawal can be exceedingly uncomfortable for the patient but, unlike alcohol and sedative-hypnotic withdrawal, is generally not life-threatening. Accordingly, the goal of opiate withdrawal treatment is relief of pain and suffering. Symptoms of opiate withdrawal include dysphoria, anxiety, irritability, craving, mydriasis, piloerection, diaphoresis, nausea, vomiting, diarrhea, rhinorrhea, lacrimation, insomnia, fever, and hypertension. Onset of this syndrome depends on the half-life of the drug used and with heroin is usually 6–8 hours after the last use.

The syndrome can last 2–5 days, depending on the individual patient. Clonidine in doses of 0.1–0.3 mg every 3 hours, up to 0.8 mg/day, can be given to suppress signs of opiate withdrawal ([Ahmadi-Abhari et al. 2001](#); [Akhondzadeh et al. 2000](#); [Charney et al. 1981](#); [Gossop 1988](#)). A major side effect of this regimen is hypotension, so the regimen must be carried out in a medically supervised setting. Clonidine should be avoided in patients who are dependent on both opiates and alcohol or a sedative-hypnotic; clonidine may mask the autonomic signs of ethanol withdrawal without actually preventing the emergence of delirium tremens. Other agents commonly utilized for symptomatic opiate withdrawal include promethazine or ondansetron, loperamide, ibuprofen, methocarbamol, and hydroxyzine.

## Psychotropic Medication Side Effects

### Antipsychotics

Several adverse events can occur in patients taking antipsychotics. Dystonic reactions are characterized by extreme muscle contraction and rigidity in a patient with stable vital signs and a clear sensorium. These occur most frequently with high-potency first-generation antipsychotics ([Moleman et al. 1982](#); [Schillevoort et al. 2001](#)). Young males are particularly susceptible to dystonic reactions. Most dystonic reactions are extremely uncomfortable and frightening to the patient. Treatment of these reactions is typically 1–2 mg of benztropine via the oral or intramuscular route. An alternative is diphenhydramine in doses of 25–50 mg via the oral or intramuscular route. Dystonias that include the eyes, the so-called oculogyric

crises, are particularly frightening, as are dystonias that cause laryngeal spasms, which can compromise the airway. These reactions should be treated with 50 mg of intramuscular diphenhydramine, which provides rapid relief. Maintenance treatment of 1-2 mg of benztropine twice a day or 25-50 mg of diphenhydramine twice a day should be initiated after the acute reaction has resolved ([Keepers et al. 1983](#)).

Akathisia is a syndrome characterized by internal restlessness, often perceived as the need to be in motion. This leads to increased psychomotor activity, including pacing, rocking, leg tapping and bouncing, and moving frequently between sitting and standing. The patient may complain of feeling anxious or irritable, or of having the sensation that his or her “skin is crawling.” Lowering the dosage of the antipsychotic or switching to a second-generation antipsychotic are treatment options. Propranolol in doses of 10 mg two or three times a day is an effective treatment for akathisia.

Neuroleptic malignant syndrome (NMS) is a potentially fatal delirium that develops in some patients in response to antipsychotic agents ([Susman 2001](#)). The diagnosis is made on the triad of symptoms of altered level of consciousness, muscular rigidity (often described as lead-pipe rigidity), and autonomic instability. The autonomic instability includes hyperthermia, tachycardia, labile blood pressure, diaphoresis, incontinence, and occasional dysphagia and bowel obstruction. Associated findings include elevated creatine phosphokinase (CPK), elevated white blood cell count, and metabolic acidosis. Later complications include rhabdomyolysis and renal failure. The main interventions in NMS are discontinuation of the offending agent and provision of general supportive measures, including

cooling, rehydration, intensive nursing care, and anticoagulation. A few drugs have been used to treat NMS, including benzodiazepines, bromocriptine (15 mg/day), dantrolene (100–300 mg/day), and amantadine (200 mg/day). ECT also has been used to treat NMS.

The atypical antipsychotic clozapine can cause catastrophic agranulocytosis in up to 1% of patients treated. This usually occurs within 6 weeks to 6 months of initiating therapy with clozapine. A white blood cell count of less than  $3,500/\text{mm}^3$  or a granulocyte count of less than  $1,500/\text{mm}^3$  warrants discontinuation of the medication. Other signs of impending marrow failure are fever, flulike symptoms, and sore throat. Discontinuation of the clozapine, supportive measures, and treatment of specific infections if identified are the main interventions for agranulocytosis, and in life-threatening cases, growth factors (filgrastim [Neupogen]) can be used.

## **Antidepressants**

Adverse events associated with tricyclic antidepressants include anticholinergic delirium, cardiac conduction delays, and seizures. Anticholinergic delirium is more common in elderly and impaired individuals and may be potentiated by concomitant anticholinergic medications. The principal intervention is to decrease or discontinue the offending agent. Furthermore, the coadministration of an SSRI or other drug known to inhibit the cytochrome P450 2D6 enzyme with a tricyclic antidepressant can cause dramatic increases in tricyclic antidepressant blood levels and resultant delirium. These drugs also can affect cardiac conduction, can lower seizure thresholds, and are lethal in overdose.

A hypertensive crisis can occur in a patient who is taking monoamine oxidase inhibitors. This usually happens after ingestion of a large dose of tyramine (which can be found in certain food products) or after an interaction with another drug (e.g., meperidine, other antidepressants, sympathomimetic agents). Discontinuation of the monoamine oxidase inhibitor and management of the hypertension are the appropriate treatments.

Serotonin syndrome is a delirium characterized by altered level of consciousness, autonomic instability, and neuromuscular abnormalities including myoclonus, hyperreflexia, nystagmus, akathisia, and muscle rigidity ([Martin 1996](#); [Mason et al. 2000](#)). Several different drugs, usually administered in combination, can cause this adverse event. Drugs reported to provoke serotonin syndrome include SSRIs, tricyclic antidepressants, monoamine oxidase inhibitors, venlafaxine, trazodone, nefazodone, lithium, tryptophan, meperidine, sumatriptan, buspirone, duloxetine, milnacipran, and amphetamines. Discontinuation of the offending agent and general supportive measures are the principal interventions. Unlike in NMS, bromocriptine can worsen the serotonin syndrome. Other drugs useful in treating this condition are benzodiazepines, cyproheptadine, chlorpromazine, methysergide, and propranolol.

Although not a life-threatening emergency, SSRI discontinuation syndrome can be very frightening and distressing to patients. This syndrome develops after abrupt discontinuation of a short-half-life SSRI, with paroxetine and venlafaxine the two most common agents. Symptoms include dizziness, malaise, nausea, paresthesias, tremor, ataxia, confusion, myoclonus, anxiety, and vivid dreaming. Symptoms usually develop 48 hours after the last dose,

peak around day 4-5, and can last as long as 2 weeks. Interventions include reassuring the patient and restarting the medicine, followed by a very gradual taper.

Priapism is a rare but potentially serious adverse event that has been associated with psychotropic medications including trazodone. This physiological condition is usually self-limiting. However, a patient with an erection lasting for more than 4 hours warrants an evaluation and treatment by appropriate medical personnel ([Montague et al. 2003](#)). Patients should be warned of this rare but serious potential side effect.

---

## Conclusion

---

In the modern era, with changes in the mental health care delivery systems and the resultant limitations placed on the utilization of inpatient treatment resources, the emergency psychiatrist will increasingly be called upon to diagnose and initiate definitive treatment of patients with a wide range of psychiatric disorders. Emergency psychiatrists must balance the needs of individual patients with those of the larger community, the health care system, and the third-party payer system, with a focus on delivering care that is both efficacious and cost-effective. This requires a broad knowledge base, incorporating elements of all branches of psychiatry, and consideration of thorough yet expeditious evaluation, diagnosis, and treatment of patients with mental illnesses.

## CHAPTER 59

# Treatment of Agitation and Aggression in the Elderly

Carl Salzman, M.D.

Severe behavioral agitation and aggression—including restlessness, wandering, assaultiveness, or screaming—may accompany late-life psychosis, dementia, or mood disorders, with particularly high prevalence rates in nursing homes. Severely depressed or very anxious elderly individuals can also become behaviorally disruptive, endangering themselves and others as well as decreasing the quality of their lives ([Banerjee et al. 2006](#)). Behavioral and psychiatric symptoms develop in more than half of community-dwelling patients with dementia ([Lyketsos et al. 2000](#)), and virtually all individuals with dementia will display behavioral complications at some point. In nursing homes, rates of behavioral and psychiatric symptoms are estimated to be as high as 80% in patients with dementia

([Testad et al. 2007](#); [Zuidema et al. 2007](#)); over the course of a lifetime, the risk of these symptoms is estimated at 100% ([Lyketsos et al. 2000](#)).

Serious behavioral symptoms, especially those associated with psychosis and dementia, may have devastating consequences for patients and their families. Such symptoms decrease the quality of life for the patient and family ([Matsui et al. 2006](#)) and may indicate a worse prognosis. Although various medications have been employed to treat disruptive behavior in elderly patients, no medications have been approved by the U.S. Food and Drug Administration (FDA) for this specific therapeutic indication. Antipsychotic drugs have been frequently used off-label for this purpose; however, these drugs can cause serious side effects in some patients. Other medications that have been tried, without reliable success, include antidepressants, mood stabilizers, cognitive enhancers, and even benzodiazepines.

---

## Antipsychotic Medications

---

Despite a growing awareness of the potential hazards of antipsychotic medications, these drugs are still the mainstay of pharmacological treatment given to elderly individuals with dementia who are agitated or psychotic ([Ballard et al. 2014](#)). In previous years, conventional antipsychotics (also known as first-generation antipsychotics [FGAs]) such as haloperidol were used to help control serious agitated behaviors. In recent years, the so-called atypical antipsychotics (also known as second-generation antipsychotics [SGAs]) have become the primary

psychopharmacological approach to management of this difficult clinical state. Haloperidol and other FGAs have been shown to have higher rates of side effects and possible increased rates of mortality compared with the newer SGA drugs. Unfortunately, both FGA and SGA medications produce only modest benefits and carry a potential for serious adverse effects and inappropriate use ([Jeste et al. 2005](#)). As a general prescribing guideline, antipsychotic drug dosages used for elderly adults should be considerably lower than those used for younger and middle-aged adults.

SGAs are as effective as FGAs for late-life psychotic symptoms as well as for management of agitation and aggression with or without associated psychosis ([Ballard and Waite 2006](#); [Sink et al. 2005](#)). Because of their more benign side-effect profile, the SGAs are now the preferred first-choice medications for management of behavioral symptoms in the elderly. Nonetheless, the overall efficacy of antipsychotic drugs in controlling serious behavioral and psychotic disturbance is modest; even with treatment, many older individuals with dementia continue to display behavioral and affective dyscontrol, especially when stressed, as well as in the evenings (i.e., sundowning). As a generalization, studies comparing SGAs with FGAs have reported greater efficacy for the SGAs ([Lopez et al. 2013](#)), and in all studies, the SGAs were associated with fewer extrapyramidal side effects (EPS) than the FGAs ([Chan et al. 2001](#)).

Pharmacological treatment of the aggression, agitation, and behavioral disruption commonly seen in moderate to severe dementia is difficult. Despite the obvious need for safe and effective pharmacological approaches, no drugs have been approved by the FDA for the management of persisting agitation or aggression associated with

dementia. In one large study (the Clinical Antipsychotic Trials of Intervention Effectiveness—Alzheimer’s Disease [CATIE-AD]), overall response rates ranged from 48% to 65% with olanzapine treatment versus 30%–48% with placebo, showing an incremental treatment benefit of about 18% for active drug over placebo ([Schneider et al. 2006](#)), although olanzapine was associated with worsening of cognition ([Vigen et al. 2011](#)). Other SGA medications also reported to be beneficial for disruptive behavior in the context of dementia include aripiprazole ([Coley et al. 2009](#)), ziprasidone ([Greco et al. 2005](#)), olanzapine ([Street et al. 2000](#)), risperidone ([Brodaty et al. 2003](#); [Devanand et al. 2012](#)), and quetiapine ([Tariot et al. 2006](#)).

All antipsychotic medications produce side effects, and in general, elderly individuals are more susceptible and sensitive to these effects. For this reason, drugs with anticholinergic or orthostatic hypotensive properties (e.g., clozapine) should be avoided in the elderly whenever clinically possible. Because many antipsychotics are substrates of cytochrome P450-metabolizing enzymes, caution must also be exercised regarding the potential for adverse drug interactions.

In the early years of the twenty-first century, evidence pointing to increased rates of morbidity and early death in elderly individuals receiving antipsychotic drugs generated considerable concern. An initial report indicating a heightened risk of cerebrovascular adverse events (CVAEs; e.g., stroke, transient ischemic attack [TIA], death) in male nursing home residents older than 85 years who were treated with risperidone ([Wooltorton 2002](#)) prompted further investigation. Similar suggestive evidence was reported for olanzapine, and ultimately for other SGAs ([Kryzhanovskaya et al. 2006](#)). Taken together, these

observations of increased CVAEs in elderly individuals receiving SGAs stimulated an examination of all studies. The findings supported the concerns regarding a possible increased risk of CVAEs associated with use of risperidone or olanzapine in elderly patients with dementia. Data from 11 olanzapine or risperidone studies collectively suggested that 2.2% of drug-treated subjects experienced CVAEs, compared with 0.8% of placebo-treated subjects. The combined relative risk was 2.7. [Ballard and Waite \(2006\)](#) concluded that despite the modest efficacy of these drugs, the significance of the adverse events dictated that “neither risperidone nor olanzapine should be used routinely to treat dementia patients with aggression or psychosis unless there is marked risk or severe distress.”

In 2003, the FDA issued a black box warning regarding a possible increased risk of CVAEs associated with use of atypical antipsychotics in older adults with dementia. The warning was eventually extended to include aripiprazole, olanzapine, and risperidone. The death rate in clinical trials was 3.5% with SGAs versus 2.3% with placebo, leading the FDA to impose a black box warning for all antipsychotics. Studies examining large public databases ([Ballard and Waite 2006](#); [Schneider et al. 2006](#)) have found similar rates of death among elderly people receiving FGAs ([Schneeweiss et al. 2007](#); [Wang et al. 2005](#)). Causes of death vary, but most of the deaths appear to be cardiovascular (e.g., heart failure, sudden death) or infectious (e.g., pneumonia) in nature.

The FDA warning has generated considerable controversy. Some observers concur with the FDA warning suggesting that mortality is increased ([Kales et al. 2012](#)) in a dose-dependent fashion ([Ballard et al. 2014](#)). Other researchers, examining the data on which the FDA's

warning was based, have become concerned that methodological faults in many of the studies may have compromised the meta-analyses and led to an overly harsh interpretation of the data and an unwarranted concern for safety. Some studies failed to find an increase in death rate or incidence of CVAEs. For example, [Herrmann et al. \(2004\)](#), as well as [Haupt et al. \(2006\)](#), [Raivio et al. \(2007\)](#), and [Gill et al. \(2005\)](#), found no significant increase in the risk of ischemic stroke with either FGAs or SGAs or among those receiving SGAs compared with FGAs. The American College of Neuropsychopharmacology issued a White Paper ([Jeste et al. 2008](#)) concluding that further research data are needed to clarify the ongoing significance, if any, of increased development of CVAEs with SGAs. An expert consensus conference held in 2006 ([Salzman et al. 2008](#)) essentially made the same point. It is clear that not all individuals with dementia who receive antipsychotic medication for disruptive symptoms have an increased risk of premature mortality ([Devanand 2013](#)).

When confronted with elderly patients with dementia who are possibly psychotic and who are manifesting extreme agitation and/or aggression, clinicians face a difficult treatment dilemma. The essential conclusion of the CATIE-AD study, and a sensible statement about the role of antipsychotics in management of behavioral symptoms in dementia ([Jeste et al. 2008](#); [Salzman et al. 2008](#); [Sink et al. 2005](#)), was that on average, patients receive modest benefit from these agents without being harmed: these are the patients for whom continued therapy is rational. The following clinical conclusions appear to be warranted at present:

1. Recognizing that the use of antipsychotic drugs to treat agitation or aggression is “off label,” clinicians must be certain that the behavior cannot be managed nonpharmacologically and that the severity of the disruptive behavior warrants the selection of antipsychotic medications.
2. SGAs are still preferred to FGAs because of the former’s lower likelihood of EPS and tardive dyskinesia.
3. Clinicians should confer with the patient’s family or significant others regarding the use of these drugs and should attempt to obtain some type of informed consent, balancing the possible risks of using these medications against the likelihood of worsening behavior and clinical status without such treatment.
4. Clinicians should closely follow patients receiving antipsychotics for early warning signs of a CVAE.
5. Antipsychotic medications are often prescribed at dosages that are too high for elderly individuals, especially those with dementia. Clinicians should strive to use the lowest therapeutic doses. If necessary, liquid preparations can facilitate very-low-dose administration.
6. Clinicians should be mindful of an elderly individual’s medical status and medication treatment to avoid unwanted side effects of drug interactions due to polypharmacy.

The American Psychiatric Association Practice Guideline on the Use of Antipsychotics to Treat Agitation or Psychosis in Patients with Dementia ([Reus et al. 2016](#)) notes that antipsychotic medication may be modestly helpful, but emphasizes that medication must be part of a comprehensive program of medical care that includes careful medication monitoring.

---

## Other Medication Classes

---

An increasing number of other medication classes are being used as second-line choices for management of agitation and aggression, but with less reliable effectiveness ([Salzman et al. 2008](#)). These include trazodone, benzodiazepines, anticonvulsants (mood stabilizers), serotonergic antidepressants, and cognitive enhancers.

### Trazodone

The antidepressant drug trazodone was reported to be effective in treating agitation and severely disruptive behavior ([Pinner and Rich 1988](#); [Seitz et al. 2011](#); [Tariot 1996](#)), although these studies did not distinguish between psychotic and nonpsychotic patients. Extensive clinical experience suggests that trazodone is effective at dosages of 50–200 mg/day, with few side effects other than sedation. The mechanism of trazodone's effect is unknown. Current clinical experience continues to suggest that trazodone is often extremely helpful as an add-on medication when antipsychotics or other drugs alone cannot control disruptive behavior. Priapism is a rare side effect of trazodone in elderly men.

### Benzodiazepines

Although benzodiazepines are quite widely used in the elderly agitated population, there have been no studies of benzodiazepine treatment of agitation or aggression in nearly a decade. Most of the older studies were not placebo

controlled, but they nonetheless suggested that on average, agitation could be reduced with short-term benzodiazepine therapy (Loy et al. 1999). For example, Coccaro et al. (1990) compared oxazepam (10–60 mg/day) with low-dose haloperidol in patients with dementia diagnoses. Five percent of patients in the benzodiazepine group improved, compared with 24% of those in the haloperidol group, a difference that was not statistically significant, perhaps because of the small sample size. Christensen and Benfield (1998) compared alprazolam (0.5 mg twice daily) with haloperidol (0.6 mg/day) in a crossover study. Adverse events were not significantly different between groups. The dosages of both agents used in this study were probably too low to expect an effect, and none was seen. Meehan et al. (2002) noted that intramuscular lorazepam 1.0 mg or 0.5 mg was superior to placebo at 2 hours but not at 24 hours.

Possible side effects of benzodiazepines in elderly individuals include ataxia, falls, confusion, anterograde amnesia, sedation, light-headedness, and tolerance and withdrawal syndromes. There is evidence that mild anterograde amnesia may occur in elderly patients who are taking therapeutic doses of a benzodiazepine, although this side effect is often reversible (Salzman et al. 1992). A recent review suggests that benzodiazepines may increase the risk of developing Alzheimer's disease (Billioti de Gage et al. 2014), although this finding is controversial (Salzman and Shader 2015). Nevertheless, the potential side effects of benzodiazepines in the context of scant evidence of efficacy suggest that their use for agitation should be time limited or on a low-dose, as-needed basis, with chronic use reserved for those patients in whom other agents have proved ineffective. Benzodiazepines with simpler

metabolisms and relatively short half-lives, such as lorazepam and oxazepam, are always preferred.

## Anticonvulsants

Although early studies reported benefit for carbamazepine in elderly patients with agitation ([Tariot et al. 1994](#)), most subsequent studies suggested that anticonvulsants are not reliably helpful for controlling agitation and aggression in elderly individuals, especially those with dementia. Small clinical observation studies have reported a modest benefit for divalproex, as well as for lamotrigine, but subsequent experience has not borne out the clinical usefulness of these agents.

## Serotonergic Antidepressants, Cognitive Enhancers, and Their Combination

Although disappointing experience has been reported for serotonergic antidepressants, the combination of a selective serotonin reuptake inhibitor (SSRI) antidepressant and a cognitive-enhancing cholinesterase inhibitor is commonly used in an effort to control agitation without resorting to use of antipsychotics. However, clinical experience suggests that this combination has inconsistent, modest efficacy ([Holmes et al. 2004](#)).

## New Approaches

A new approach to the treatment of dementia-related agitation has recently been published. In a preliminary 10-week Phase II randomized clinical trial of patients with probable Alzheimer's disease, combination dextromethorphan-quinidine demonstrated clinically relevant efficacy for agitation and was generally well tolerated ([Ballard et al. 2015](#); [Cummings et al. 2015](#)).

Another recent study suggested that some patients with Alzheimer's disease accompanied by aggression or agitation may respond to citalopram 20–30 mg/day ([Peters et al. 2016](#); [Schneider et al. 2016](#)). The authors noted a significant clinical heterogeneity of agitation and aggression in this disorder that made specific symptoms or identifying patient data predict response or nonresponse. Residence in long-term care, however, was associated with a negative outcome with citalopram. Patients for whom citalopram was more effective were more likely to be outpatients, to have the least cognitive impairment, to have moderate agitation, and to be in the age range of 76–82 years.

---

## Conclusion

---

Dementia-associated agitation is common and can be difficult to treat. The usual first-choice medications are the antipsychotics, but they have only modest efficacy and may cause significant side effects. New treatment guidelines do not favor these drugs, although clinicians may find that the other choices are less effective. Trazodone is a useful second choice or an addition to the antipsychotics. Anticonvulsants have an uncertain therapeutic effect; initial

data were promising, but subsequent experience and further research has not supported their routine use. Benzodiazepines and other sedative-hypnotics are generally not recommended for the behavioral treatment of individuals with dementia or agitation. Cognitive enhancers, alone or in combination with SSRI antidepressants, are commonly used, but their therapeutic effect is unreliable and usually inadequate when behavioral disruption is severe or frequent. Most recently, the report of treatment success with a dextromethorphan-quinidine combination has raised hopes that treatment of this difficult behavioral problem associated with dementia may be making progress.

## Psychiatric Medications

Robert H. Chew, Pharm.D.

Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
ANTIDEPRESSANTS				
Tricyclic and tetracyclic antidepressants				
Secondary tricyclics				
Desipramine (Norpramin)	MDD	100-200 mg/day (at bedtime or in divided doses)	300	Ages 10-17: 100 mg/day (at bedtime or in divided doses)

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.  
*Source.* Athenahealth Inc.: epocrates®; Available at: <http://online.epocrates.com>; Findling R. *Adolescent Psychopharmacology*. Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
Nortriptyline (Pamelor)	MDD	75-100 mg/day (once daily or divided tid-qid)	150	Ages 18-64: 75-100 mg/day (once daily or divided tid-qid); Ages 65-74: 75-100 mg/day (once daily or divided tid-qid); Ages 75+: 75-100 mg/day (once daily or divided tid-qid)
Protriptyline (Vivactil)	MDD	15-40 mg/day (divided tid-qid)	60	Ages 18-64: 15-40 mg/day (divided tid-qid); Ages 65-74: 15-40 mg/day (divided tid-qid); Ages 75+: 15-40 mg/day (divided tid-qid)
<b><i>Tertiary tricyclics</i></b>				
Amitriptyline (Elavil)	MDD	50-150 mg/day (at bedtime or in divided doses)	300	Ages 18-64: 50-150 mg/day (at bedtime or in divided doses); Ages 65-74: 50-150 mg/day (at bedtime or in divided doses); Ages 75+: 50-150 mg/day (at bedtime or in divided doses)
	MDD, hospitalized patients	100-200 mg/day (at bedtime or in divided doses)	300	

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; qid=four times daily (or divided into 4 doses); SL=sublingual; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release. Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
Clomipramine (Anafranil)	OCD	150-250 mg/day (at bedtime or in divided doses)	250	Ages 12 and older: 200 mg, bid in divided doses
Doxepin	Depression and/or anxiety			
	Mild-moderate symptoms	75-150 mg/day (at bedtime or in divided doses)	150	
	Severe symptoms	300 mg/day (at bedtime or in divided doses)	300	
Doxepin tablets (Silenor)	Insomnia	3-6 mg at bedtime	6	
Imipramine (Tofranil)	MDD	50-150 mg/day (at bedtime or in divided doses)	200	Ages 12 and older: 40 mg, bid or in divided doses
	MDD, hospitalized patients	250-300 mg/day (in divided doses)	300	

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.

Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
	Nocturnal enuresis			Ages 5-10 years: 50 mg/day; 10-15 years: 75 mg/day; 15 years and older: 100 mg/day
Trimipramine (Surmontil)	MDD	50-150 mg/day (at bedtime or in divided doses)	200	Ages 10-15 years: 100 mg/day; 15 years and older: 200 mg/day
	MDD, hospitalized patients	250-300 mg/day (at bedtime or in divided doses)	300	
<b>Tetracyclines</b>				
Amoxapine	MDD	200-300 mg/day (at bedtime or in divided doses)	400	
	MDD, hospitalized patients		600	
Maprotiline	MDD	75-150 mg/day (at bedtime or in divided doses)	150	

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release; *Source.* Athenahealth Inc.: epocrates®; Available at: <http://online.epocrates.com>; Findling R. *Adolescent Psychopharmacology*. Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
	MDD, hospitalized patients	150-225 mg/day (at bedtime or in divided doses)	225	
<b>Selective serotonin reuptake inhibitor (SSRI) antidepressants</b>				
Citalopram (Celexa)	MDD	20-40 mg/day	40	
Escitalopram (Lexapro)	MDD	10-20 mg/day	20	Ages 18 and older
	GAD	10-20 mg/day	20	
Fluoxetine (Prozac)	MDD	20-80 mg/day in morning or divided bid; or 90 mg weekly <sup>†</sup>	80	Ages 18 and older
	OCD	20-60 mg/day in morning or divided bid	80	Ages 18 and older
	Panic disorder	20-60 mg/day	60	
	Bulimia nervosa	20-60 mg/day	60	

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); SL=sublingual; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.

Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
Fluoxetine (Sarafem)	PMDD	20-60 mg/day <sup>†</sup>	80	
Fluvoxamine	OCD	100-300 mg/day (divided bid)	300	Ages 18-29 years: 200 mg/day (divided bid); Ages 30-39 years: 300 mg/day (divided bid)
Fluvoxamine extended-release (Luvox CR)	OCD	100-300 mg/day at bedtime	300	
Paroxetine (Paxil)	MDD	20-50 mg/day in morning	50	
Paroxetine extended-release (Paxil CR)	MDD	ER: 25-62.5 mg/day	62.5	
	GAD	20-50 mg/day	50	
	Social anxiety disorder	20-60 mg/day	60	Ages 18-29 years: 60 mg/day
		ER: 12.5-37.5 mg/day	37.5	in morning

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); SL=sublingual; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.

Medication	Approved indications	Adult		Usual dosage
		Usual dosage	Maximum (mg/day)	
	Panic disorder	40 mg/day in morning ER: 12.5-75 mg/day in morning	60-75	
	OCD	20-60 mg/day in morning	60	Ages 18-60 mg/day in morning
	PTSD	20-50 mg/day in morning	50	
	PMDD	ER: 12.5-25 mg/day in morning <sup>†</sup>	25	
Sertraline (Zoloft)	MDD	50-200 mg/day in morning	200	Ages 18-60 mg/day in morning
	Social anxiety disorder	50-200 mg/day	200	
	Panic disorder	50-200 mg/day in morning	200	
	OCD	50-200 mg/day in morning	200	Ages 18-60 mg/day in morning

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.

## AGENTS FOR TREATMENT OF INSOMNIA

### Benzodiazepines

Estazolam		1-2 mg at bedtime	2
Flurazepam (Dalmane)		15-30 mg at bedtime	30
Quazepam (Doral)		7.5-15 mg at bedtime	15
Temazepam (Restoril)		7.5-30 mg at bedtime	30
Triazolam (Halcion)		0.125-0.5 mg at bedtime	0.5; 0.25 in elderly

### Nonbenzodiazepines

Eszopiclone (Lunesta)		1-3 mg at bedtime	3
Ramelteon (Rozerem)		8 mg at bedtime	8
Suvorexant (Belsomra)		10-20 mg at bedtime	20
Tasimelteon (Hetlioz)	Non-24-hour sleep-wake disorder	20 mg at bedtime	20

*Note.* ADHD=attention-deficit/hyperactivity disorder; CYP2D6=cytochrome P450 2D6 enzyme; GAD=generalized anxiety disorder; MDD=major depressive disorder; OCD=obsessive-compulsive disorder; PTSD=posttraumatic stress disorder.

—=not available; bid=twice daily (or divided into 2 doses); IM=intramuscular; IV=intravenous; tid=three times daily (or divided into 3 doses); qid=four times daily (or divided into 4 doses); SL=sublingual; tid=three times daily (or divided into 3 doses); CD=controlled delivery (extended release); CR=controlled release (extended release); ER=extended release; LA=long acting (extended release); SR=sustained release (extended release); XL, XR=extended release.

Clobazam

- for generalized anxiety disorder, [590](#)
- interaction with carbamazepine, [966](#)
- structure of, [1053](#)

Clomethiazole, [1068](#)

Clomipramine

- in children and adolescents, [1211](#), [1448–1449](#), [1470–1471](#)
- dosing of, [311](#), [1633](#)
- drug interactions with
  - carbamazepine, [965](#)
  - SSRIs, [318](#), [425](#)
- indications for

- autism spectrum disorder, 1470-1471
- depression, 316
  - in elderly persons, 391
  - vs. paroxetine, 390
- maintenance treatment for panic disorder, 1198
- OCD, 306, 318, 342, 396, 1210-1211
  - in children and adolescents, 1211, 1448-1449
  - cognitive-behavioral therapy and, 1212
  - fluvoxamine and, 1211
  - intravenous clomipramine, 1211
  - maintenance treatment/relapse prevention, 1211
- pain syndromes, 319
- overdose of, 324
- pharmacokinetics of, 311
- pharmacological profile of, 306, 308
- side effects of, 321, 324, 1448, 1449
- structure-activity relations for, 306, 307, 337

Clonazepam, 572

- dosing of, 1641
- drug interactions with
  - bupropion, 506
  - carbamazepine, 963, 966
  - oxcarbazepine, 963
- duration of action of, 568
- indications for
  - acute trauma exposure, 1604
  - benzodiazepine withdrawal, 1198
  - extrapyramidal side effects, 866, 867
  - insomnia, 1353, 1364
  - OCD, 1211-1212
    - in children and adolescents, 1450
  - panic disorder, 563, 568, 1196
    - in children and adolescents, 1445
  - psychotic agitation, 569
  - social anxiety disorder, 1200, 1204
    - maintenance treatment, 1203
  - specific phobia, 1204
  - tardive dyskinesia, 866, 867, 874-875
- pharmacokinetics of, 566
- side effects of, 1364

Clonidine

- in children and adolescents, 1451, 1454-1455, 1459-1460, 1472, 1500

- dosage and monitoring of, 1500, **1657**
- side effects of, 1500
- contraindications to, 1614
- discontinuation of, 1500
- drug interactions with
  - methylphenidate, 1500
  - TCAs, 325
  - trazodone, 459
- growth hormone release induced by, 165
- indications for
  - ADHD, 76, 1454–1455, 1456, 1500
    - with aggression, 1459–1460
  - akathisia, 870–871
  - autism spectrum disorder, 1472
  - borderline personality disorder, 1323
  - opioid withdrawal, 76, 1291, 1613–1614
  - PTSD in children and adolescents, 1451
  - smoking cessation, 1298
  - Tourette syndrome, 1460–1461, 1500
- overdose of, 1500
- side effects of, 871, 1454, 1500
- transdermal, 1451, 1461, 1472, 1500
- Clopidogrel, interaction with bupropion, 506
- Clorazepate
  - dosing of, **1641**
  - for generalized anxiety disorder, 589–590
  - pharmacokinetics of, 564, 571–572, 1060, **1061**
  - structure of, **565**
  - sustained-release, 567
- Clorgyline, **284**, 286
- Clozapine, 623–641
  - augmentation of, 634
  - in children and adolescents, 634, 1443, 1464, 1466, **1499**
  - dosing of, 220–221, 627, **1647**
    - in children and adolescents, **1499**
  - drug interactions with, 640–641
    - carbamazepine, **963**, 966
    - fluvoxamine, 425
    - lithium, 906
    - oxcarbazepine, **963**
    - paroxetine, 404, **404**
  - in elderly persons, 1507–1508, 1516, 1521, 1525, 1528, 1624

irreversible, 283, **284**, 286–294

isocarboxazid, 294–295

mechanism of action of, 54, 55, 69

moclobemide, 295–297

overdose of, 1316

pharmacological profile of, 59, 286

phenelzine, 294

reversible, 283, **284**, 286, **287**

selectivity of, 283, **284**

selegiline hydrochloride, 215, 297–298

selegiline transdermal system, 298

side effects of, 289–290, 1159

- hypertensive crisis, 283, 291–292, 325, 1555, 1615

structure of, 283, **284**, 286, **287**

switching to/from

- SSRIs, 340, 346, 405
- venlafaxine, 523

tranylcypromine, 295

use in hepatic disease, 294

use in pregnancy and lactation, 1555

Monoamines, 46, 50, 54. *See also* Dopamine; Norepinephrine; Serotonin

Montgomery-Åsberg Depression Rating Scale (MADRS), 390, 481, 663, 665, 741, 742, 743, 745–746, 824, 846, 894, 1004, 1006, 1007, 1434, 1435, 1514

Mood stabilizers. *See also specific drugs*

antipsychotics and, 230, 611–612

in children and adolescents, 1501–1502

dosage and monitoring of, 1501, 1501

side effects of, 1501–1502

gabapentin, 983–990, 995

indications for

autism spectrum disorder, 1471–1472

borderline personality disorder, 1320, 1323, 1324–1325, 1327

mania, 1177–1181

in children and adolescents, 1440–1443

lamotrigine, 1001–1012

lithium, 889–907

pregabalin, 990–995

topiramate, 1017–1031

use in pregnancy and lactation, 1555–1562

valproate, 923–936

Morphine, 99, 101, 1381, 1384, 1387, 1394, 1414

for acute stress disorder, 1219

combined with acetaminophen, 1398

combined with gabapentin, 1398

dosing of, 1387, 1388, 1389

for lumbar root pain, 1401

for osteoarthritis, 1408

tolerance to, 101

Mortality

alcohol-related, 1284

in anorexia nervosa, 666, 1344

antipsychotic-related risk in elderly dementia patients, 424, 663, 717, 774, 818, 825, 848, 1370, 1517, 1520, 1612, 1625–1626

in delirium, 1612

in neuroleptic malignant syndrome, 1257

in schizophrenia, 618

in serotonin syndrome, 346

sudden cardiac death

psychostimulants and, 1503–1504

TCAs and, 319, 323, 324

from suicide, 1155, 1596 (*See also Suicide and suicidal behavior*)

- pharmacological profile of, [755–759](#), [783](#)
  - 5-HT<sub>1A</sub>, 5-HT<sub>1D</sub>, and 5-HT<sub>2C</sub> receptor activity, [756–757](#)
  - D<sub>2</sub> and 5-HT<sub>2A</sub> receptor activity, [756](#)
  - PET receptor occupancy studies, [757–758](#), [758](#)
  - serotonin and norepinephrine transporter activity, [757](#)
- side effects and toxicology of, [773–782](#), [783](#), [1180](#), [1248](#), [1440](#), [1464](#)
  - activation effects, [774–775](#)
  - cardiovascular effects, [755](#), [780–782](#), [1248](#)
  - DRESS syndrome, [775](#)
  - extrapyramidal side effects, [669](#), [756](#), [769](#), [774](#), [776–777](#), [871](#), [873](#), [1180](#), [1255](#), [1464](#)
  - mortality risk in elderly dementia patients, [774](#)
  - tolerability profile in clinical trials, [773–774](#)
  - weight gain/metabolic effects, [695](#), [696](#), [757](#), [777–780](#), [779](#), [1253](#)
- structure–activity relations for, [755](#), [756](#)
- use in pregnancy and lactation, [774](#), [1564–1565](#)
- use in renal or hepatic disease, [760](#)
- Ziprasidone Experience in Schizophrenia in Germany/Austria (ZEISIG) study, [765](#)
- Ziprasidone Extended Use in Schizophrenia (ZEUS) study, [763](#), [778](#)
- Ziprasidone Observational Study of Cardiac Outcomes (ZODIAC), [781](#)
- ZODIAC (Ziprasidone Observational Study of Cardiac Outcomes), [781](#)
- Zolmitriptan, [1414](#)
- Zoloft. *See* [Sertraline](#)
- Zolpidem
  - in adjustment disorders, [1602](#)
  - dosing of, [1643](#)
  - in elderly patients, [1076](#), [1526](#)
  - for insomnia, [1052](#), [1076](#), [1365](#)
  - interaction with carbamazepine, [966](#)
  - mechanism of action of, [1351](#)
  - pharmacokinetics of, [213](#), [1064](#)
  - pharmacological profile of, [96](#)

side effects of, **1365**

with SSRIs for generalized anxiety disorder, **1208**

structure-activity relations for, **1057**, **1058**

Zonalon. *See* **Doxepin**

Zonisamide

for alcohol use disorder, **1023**

for binge-eating disorder, **1343**

interaction with carbamazepine and oxcarbazepine, **963**, **965**

Zopiclone, **1057**

in elderly patients, **1076**

pharmacokinetics of, **1064**

*S*-enantiomer of (*See* **Eszopiclone**)

ZT-1, as cognitive enhancer, **1042**

Zyban. *See* **Bupropion**

Zyprexa Zydis. *See* **Olanzapine**
